Figure S2 Comparison of the distribution of methane emissions from termite en mg CH<sub>4</sub> m<sup>-2</sup> day<sup>-1</sup>.  
Emission distribution from Sanderson et al. (1999), Saunois et al. (2016) and this study. The  
numbers represent the total annual termite emissions for each distribution. ..... 26

## 1 Supplementary Text 1: Atmospheric observations

### Existing satellite data other than GOSAT, already presented in the main text

#### Column average XCH<sub>4</sub> - SCIAMACHY

Between 2003 and 2012, the Scanning Imaging Absorption spectrometer for Atmospheric CartographHY (SCIAMACHY) was operated on board the ESA ENVIRONMENTAL SATellite (ENVISAT), providing nearly 10 years of XCH<sub>4</sub> sensitive to the atmospheric boundary layer (Burrows et al., 1995; Buchwitz et al., 2006; Dils et al., 2006; Frankenberg et al., 2011). These satellite retrievals were the first to be used for global and regional inverse modelling of methane fluxes (Meirink et al., 2008a; Bergamaschi et al., 2007; Bergamaschi et al., 2009). The relatively long-term record allowed the analysis of the inter-annual methane variability (Bergamaschi et al., 2013). However, the use of SCIAMACHY necessitates important bias correction, especially after 2005 (up to 40 ppb from south to north) (Bergamaschi et al., 2013; Houweling et al., 2014; Alexe et al., 2015).

#### Mid-to-upper troposphere CH<sub>4</sub> columns - IASI

In 2006, 2012 and 2018, the Infrared Atmospheric Sounding Interferometer (IASI) on board the European MetOp,A, B and C satellites have started to operate. Measuring the thermal radiation from Earth and the atmosphere in the TIR, they provide mid-to-upper troposphere columns of methane (representative of the 5-15 km layer) over the tropics using an infrared sounding interferometer (Crevoisier et al., 2009). Despite their sensitivity being limited to the mid-to-upper troposphere, their use in flux inversions has shown consistent results in the tropics with surface and other satellite-based inversions (Cressot et al., 2014).

#### Other surface based atmospheric observations

Other types of methane measurements are available. These are not commonly used to infer fluxes from global inversions (yet), but are used to verify their performance (see e.g. Bergamaschi et al. (2013)). Aircraft or balloon-borne in situ measurements can deliver vertical profiles with high vertical resolution. Some studies made use of aircraft profiles to estimate local to regional methane

emissions (e.g. Karion et al., 2015; Peischl et al., 2016; Wilson et al., 2016; Gvakharia et al., 2017). Such observations can also be used to evaluate remote sensing measurements from space or from the surface and bring them on the same scale as the in situ surface measurements (e.g., Wunch et al., 2010). Aircraft measurements have been undertaken in various regions either during campaigns (Wofsy, 2011; Beck et al., 2012; Chang et al., 2014; Paris et al., 2010), or in a recurrent mode using small aircrafts (Sweeney et al., 2015; Umezawa et al., 2014; Gatti et al., 2014) and commercial aircrafts (Schuck et al., 2012; Brenninkmeijer et al., 2007; Umezawa et al., 2012; 2014; Machida et al., 2008). Balloons can carry in situ instruments (e.g. Joly et al. (2008); using tunable laser diodes spectrometry) or air samplers such as AirCores that are rapidly developing in North America and Europe (Karion et al., 2010; Membrive et al., 2017; Andersen et al., 2018), allowing the measurement of vertical profiles up to 30 km height. New technologies have also developed systems based on cavity ring down spectroscopy (CRDS), opening a large ensemble of new activities to estimate methane emissions such as drone measurements (using a lightweight version of CRDS), as land-based vehicles for real-time, mobile monitoring over oil and gas facilities, as well as ponds, landfills, livestock, (e.g. Ars et al., 2017).

The Total Carbon Column Observing Network (TCCON) uses ground-based Fourier transform spectrometers (FTS) to measure atmospheric column abundances of CO<sub>2</sub>, CO, CH<sub>4</sub>, N<sub>2</sub>O and other molecules that absorb sunlight in the near-infrared spectral region (e.g. Wunch et al., 2011). As TCCON measurements make use of sunlight, they can be performed throughout the day during clear sky conditions, with the sun typically 10° above the horizon. The TCCON network has been established as a reference for the validation of column retrievals, like those from SCIAMACHY, GOSAT, and TROPOMI (e.g., Butz et al., 2011, Morino et al., 2011). TCCON data can be obtained from the TCCON Data Archive, hosted by CaltechDATA (<https://tccondat.org/>).

### Methane isotope observations

The processes emitting methane discriminate between its isotopologues (isotopes). The two main stable isotopes of CH<sub>4</sub> are <sup>13</sup>CH<sub>4</sub> and CH<sub>3</sub>D, and there is also the radioactive carbon isotope <sup>14</sup>C-CH<sub>4</sub>. Isotopic signatures are conventionally given by the deviation of the sample mole ratio (for example, R=<sup>13</sup>CH<sub>4</sub>/<sup>12</sup>CH<sub>4</sub> or CH<sub>3</sub>D/CH<sub>4</sub>) relative to a given standard (R<sub>std</sub>) relative to a reference ratio, given in per mil as in Eq. 1.

$$\delta^{13}\text{CH}_4 \text{ or } \delta D(\text{CH}_4) = \left( \frac{R}{R_{\text{std}}} - 1 \right) \times 1000 \quad (1)$$

For the <sup>13</sup>CH<sub>4</sub> isotope, the conventional reference standard is known as Vienna Pee Dee Belemnite (VPDB), with R<sub>std</sub>=0.0112372. The same definition applies to CH<sub>3</sub>D, with the Vienna Standard

Mean Ocean Water (VSMOW)  $R_{\text{SMOW}}=0.00015575$ . The isotopic composition of atmospheric methane is measured at a subset of surface stations (Quay et al., 1991; 1999; Lowe et al., 1994; Miller et al., 2002; Morimoto et al., 2006; Tyler et al., 2007). The mean atmospheric values are about -47‰ for  $\delta^{13}\text{CH}_4$  and -86 to -96‰ for  $\delta\text{D}(\text{CH}_4)$ .  $\delta^{13}\text{CH}_4$  measurements are made mainly on flask air samples analysed with gas-chromatograph isotope ratio spectrometry for which an accuracy of 0.05 per mil for  $\delta^{13}\text{CH}_4$  and 1.5‰ for  $\delta\text{D}(\text{CH}_4)$  can be achieved (Rice et al., 2001; Miller et al., 2002). These isotopic measurements based on air flask sampling have relatively low spatial and temporal resolutions. Laser-based absorption spectrometers and isotope ratio mass spectrometry techniques have recently been developed to increase sampling frequency and allow in situ operation (McManus et al., 2010; Santoni et al., 2012), and first continuous time series of  $\delta^{13}\text{CH}_4$  have been reported in Europe (Röckmann et al., 2016).

Measurements of  $\delta^{13}\text{CH}_4$  can help to partition the different methanogenic processes of methane: biogenic (-70‰ to -55‰), thermogenic (typically -55‰ to -25‰, but down to -70‰ considering early thermogenic gas; Milkov and Etiope, 2018) or pyrogenic (-25‰ to -15‰) sources (Quay et al., 1991; Miller et al., 2002; Fisher et al., 2011) or even the methanogenic pathway (McCalley et al., 2014).  $\delta\text{D}(\text{CH}_4)$  provides valuable information on the oxidation by the OH radicals (Röckmann et al., 2011) due to a fractionation of about 300‰. Emissions also show substantial differences in  $\delta\text{D}(\text{CH}_4)$  isotopic signatures: -200‰ for biomass burning sources versus -360 to -250‰ for biogenic sources (Melton et al., 2012; Quay et al., 1999).  $^{14}\text{C}-\text{CH}_4$  measurements (Quay et al., 1991; 1999; Lowe et al., 1988) may also help to partition for fossil fuel contribution (radiocarbon free source). For example, Lassey et al. (2007a) used more than 200 measurements of radioactive  $^{14}\text{C}-\text{CH}_4$  (with a balanced weight between Northern and Southern hemispheres) to further constrain the fossil fuel contribution to the global methane source emission to 30±2% for the period 1986-2000.

Integrating isotopic information is important to improve our understanding of the methane budget. Some studies have simulated such isotopic observations (Neef et al., 2010; Monteil et al., 2011) or used them as additional constraints to inverse systems (Mikaloff Fletcher et al., 2004; Hein et al., 1997; Bergamaschi et al., 2000; Bousquet et al., 2006; Neef et al., 2010; Thompson et al., 2015; McNorton et al., 2018). Using pseudo-observations, Rigby et al. (2012) found that Quantum Cascade Laser-based isotopic observations would reduce the uncertainty in four major source categories by about 10% at the global scale (microbial, biomass burning, landfill and fossil fuel) and by up to 50% at the local scale. Although not all source types can be separated using  $^{13}\text{C}$ ,  $\text{D}$  and  $^{14}\text{C}$  isotopes, such data bring valuable information to constrain groups of sources in atmospheric inversions, if the isotopic signatures of the various sources can be precisely assessed (Bousquet et

al., 2006, supplementary material). More recently, several studies have implemented joint  $^{13}\text{C}$  and  $^{12}\text{C}$  analyses in box models to retrieve trends in methane emissions and sinks (Schaefer et al., 2016; Rice et al., 2016; Schwietzke et al., 2016; Rigby et al., 2017; Turner et al., 2017) and Thompson et al. (2018) proposed a box model analysis including  $\text{CH}_4$ ,  $\text{C}_2\text{H}_6$ , and  $\delta^{13}\text{C}_{\text{CH}4}$ .

## 2 Supplementary Text 2: Principle of inversions

An atmospheric inversion for methane fluxes (sources and sinks) optimally combines atmospheric observations of methane and associated uncertainties, a prior knowledge of the fluxes including their uncertainties, and a chemistry-transport model to relate fluxes to concentrations (Rodgers, 2000). In this sense, top-down inversions integrate all the components of the methane cycle described previously in this paper. The observations can be surface or upper-air in situ observations, satellite and surface retrievals. Prior emissions generally come from bottom-up approaches such as process-based models or data-driven extrapolations (natural sources) and inventories (anthropogenic sources). The chemistry-transport model can be Eulerian or Lagrangian, and global or regional, depending on the scale of the flux to be optimized. Atmospheric inversions generally rely on the Bayes theorem, which leads to the minimization of a cost function as Eq. (2):

$$J(x) = \frac{1}{2} (y - H(x))^T R^{-1} (y - H(x)) + \frac{1}{2} (x - x_b)^T B^{-1} (x - x_b) \quad (2)$$

where  $\mathbf{y}$  is a vector containing the atmospheric observations,  $\mathbf{x}$  is a state vector containing the methane emissions and other appropriate variables (like OH concentrations or  $\text{CH}_4$  concentrations at the start of the assimilation window) to be estimated,  $\mathbf{x}_b$  is the prior state of  $\mathbf{x}$ , and  $H$  is the observation operator, here the combination of an atmospheric transport and chemistry model and an interpolation procedure sampling the model at the measurement coordinates.  $\mathbf{R}$  is the error covariance matrix of the observations and  $\mathbf{P}_b$  is the error covariance matrix associated to  $\mathbf{x}_b$ . The errors on the modelling of atmospheric transport and chemistry are included in the  $\mathbf{R}$  matrix (Tarantola, 1987). The minimization of a linearized version of  $J$  leads to the optimized state vector  $\mathbf{x}_a$  (Eq. 3):

$$x_a = x_b + (H^T R^{-1} H + P_b^{-1})^{-1} H^T R^{-1} (y - H(x)) \quad (3)$$

where  $\mathbf{P}_a$  is given by Eq. 4 and represents the error covariance matrix associated to  $\mathbf{x}_a$ , and  $\mathbf{H}$  contains the sensitivities of any observation to any component of state vector  $\mathbf{x}$  (linearized version of the observation operator  $H(x)$ ).

$$P_a = (H^T R^{-1} H + P_b^{-1})^{-1} \quad (4)$$

Unfortunately, the size of the inverse problem usually does not allow computing  $\mathbf{P}_a$ , which is therefore approximated using the leading eigenvectors of the Hessian of  $J$  (Chevallier et al., 2005) or from stochastic ensembles (Chevallier et al., 2007). Therefore, the optimized fluxes  $\mathbf{x}_a$  are obtained using classical minimization algorithms (Chevallier et al., 2005; Meirink et al., 2008b). Alternatively, Chen and Prinn (2006) computed monthly emissions by applying a recursive Kalman filter in which  $\mathbf{P}_a$  is computed explicitly for each month. Emissions are generally derived at weekly to monthly time scales, and for spatial resolutions ranging from model grid resolution to large aggregated regions. Spatio-temporal aggregation of state vector elements reduces the size of the inverse problem and allows the computation of  $\mathbf{P}_a$ . However, such aggregation can also generate aggregation errors inducing possible biases in the inferred emissions and sinks (Kaminski et al., 2001). The estimated  $\mathbf{x}_a$  can represent either the net methane flux in a given region or contributions from specific source categories. Atmospheric inversions use bottom-up models and inventories as prior estimates of the emissions and sinks in their setup, which make B-U and T-D approaches generally not independent.

### **3 Supplementary Text 3: Set of prior fluxes suggested by the atmospheric inversion protocol**

A set of fluxes for the different methane sources has been gathered and made available to the community to perform atmospheric inversions.

The anthropogenic emissions are from EDGARv4.3.2 database (Janssens-Maenhout et al., 2019), which is available up to 2012. For this study, the EDGARv4.3.2 was extrapolated up to 2017 using the extended FAO-CH<sub>4</sub> emissions for CH<sub>4</sub> emissions from enteric fermentation, manure management and rice cultivation, and using the BP statistical review of fossil fuel production and consumption (<http://www.bp.com/>) to update CH<sub>4</sub> emissions from coal, oil and gas sectors. In this extrapolated inventory, called EDGARv4.3.2<sub>EXT</sub>, methane emissions for year  $t$  are set up equal to the 2012 EDGAR CH<sub>4</sub> emissions ( $E_{EDGARv4.3.2}$ ) times the ratio between the FAO-CH<sub>4</sub> emissions (or BP statistics) of year  $t$  ( $E_{FAO-CH4}(t)$ ) and FAO-CH<sub>4</sub> emissions (or BP statistics) of 2012 ( $E_{FAO-CH4}(2012)$ ). For each emission sector, the region-specific emissions ( $E_{EDGARv4.3.2ext}$ ) in year ( $t$ ) are estimated following Eq. (1):

$$E_{EDGARv4.3.2}(t) = E_{EDGARv4.3.2}(2012) \times E_{FAO-CH4}(t)/E_{FAO-CH4}(2012) \quad (1)$$

Transport, industrial, waste and biofuel sources were linearly extrapolated based on the last three years of data while other sources are kept constant at the 2012 level. This extrapolation approach is

necessary, and often performed by top-down approaches to define prior emissions, because, up to now, global inventories such as sector-specific emissions in the EDGAR database are not updated on a regular basis.

Biomass burning from GFED4.1s was provided on a monthly basis up to 2017.

For wetland emissions, the mean of 11 models of Poulter et al., (2017) from the GCP-CH<sub>4</sub> BU group was calculated and provided as monthly global CH<sub>4</sub> emissions.

Emissions for termites are from the model described in Kirschke et al. (2013), and represent a climatological estimate.

Emissions from oceans are from Lambert and Schmidt (1993), emissions from geological sources are from a climatology map based on Etiope (2015). The soils uptake is from climatology of Ridgwell et al. (1999).

#### **4 Supplementary Text 4: Wetland emissions from land surface models and wetland extent**

Land surface models estimate CH<sub>4</sub> emissions through a series of processes, including CH<sub>4</sub> production, CH<sub>4</sub> oxidation and transport and are further regulated by the changing environmental factors (Tian et al., 2010; Xu et al., 2010; Melton et al., 2013; Wania et al., 2013; Poulter et al., 2017). In these models, methane emissions from wetlands to the atmosphere are computed as the product of an emission flux density (which can be negative; mass per unit area and unit time) multiplied by a wetland extent; see the model inter-comparison studies by Melton et al. (2013) and Bohn et al. (2015). The CH<sub>4</sub> emission flux density is represented in land surface models with varying levels of complexity (Wania et al. 2013). Many biogeochemical models link CH<sub>4</sub> emissions with net primary production though production of exudates or litter or to soil carbon to yield heterotrophic respiration estimates, although models with more explicit microbial representations of methane production are now being applied (Grant et al., 2019). A proportion of the heterotrophic respiration estimate is then taken to be CH<sub>4</sub> production (Melton et al., 2013), with this proportion calibrated to match regional estimates from aircraft campaigns or global estimates from atmospheric inversions. The oxidation of produced (and becoming atmospheric) methane in the soil column is then either represented explicitly (e.g., Riley et al. (2011), Grant and Roulet (2002)), or fixed proportionally to production (Wania et al., 2013).

In land surface models, wetland extent is either ‘diagnostic’ and prescribed (from inventories or remote sensing data) or ‘prognostic’ and computed numerically (using hydrological models accounting for the fraction of grid cell with flat topography prone to high-water table (e.g., Stocker et al. (2014), Kleinen et al. (2012)). Hybrid approaches can also be implemented with tropical extent prescribed from remote sensing and northern peatland extent explicitly computed (Zhang et al., 2016; Melton et al., 2013). Wetland extent appears to be a primary contributor to uncertainties in methane emissions from wetlands (Bohn et al., 2015, Desai et al., 2015). For instance, the maximum wetland extent on a yearly basis appeared to be very different among prognostic simulations from land surface models (ranging from 7 to 27 Mkm<sup>2</sup>, Melton et al. (2013)), leading to larger uncertainty in derived methane emissions compared to model ensemble using the same prescribed wetland extent from remote sensing observations (Poulter et al., 2017).

Passive and active remote sensing data in the microwave domain have been used to retrieve inundated areas, as with the Global Inundation Extent from Multi-Satellites product (GIEMS, Prigent et al. (2007), Papa et al. (2010)). These remote-sensed data do not exactly correspond to wetlands, as not all flooded areas are wetlands (in the methane emission sense) and some wetlands (e.g. northern bogs) are not always flooded. Inundated areas also include inland water bodies (lakes, ponds, streams, estuaries) and rice paddies, which have to be filtered out to compute wetland emissions. Overall, current remote sensing of wetlands tends to underestimate wetland extent partly because of the spatial resolution of the current satellite passive microwave observations (of the order of 20 km spatial resolution) and partly because microwave signals only detect water above or at the soil surface and therefore do not detect non-inundated, CH<sub>4</sub> emitting peatlands (Prigent et al., 2007). For example, the Global Lakes and Wetlands Dataset (GLWD) (Lehner and Döll, 2004), estimates between 8.2 and 10.1 Mkm<sup>2</sup> of wetlands globally, while remote sensing inundation area is smaller, i.e., ~6 Mkm<sup>2</sup> (Prigent et al., 2007), but with recent estimates up to 30 Mkm<sup>2</sup> (Tootchi et al., 2019).

**Table S1 List of the countries used to define the 18 continental regions**

<b>Region num.</b>	<b>Region name</b>	<b>Countries or territories</b>
1	USA	USA with Alaska, Bermuda Islands
2	Canada	Canada
3	Central America	Anguilla, Antigua and Barbuda, Bahamas, Barbados, Belize, British Virgin Islands, Cayman Islands, Costa Rica, Cuba, Dominica, Dominican Republic, El Salvador, Guadeloupe, Guatemala, Honduras, Jamaica, Martinique, Mexico, Montserrat, Nicaragua, Panama, Puerto Rico, Saint Kitts and Nevis, Saint Lucia, Saint Vincent and the Grenadines, Turks and Caicos Islands, United States Virgin Islands
4	Brazil	Brazil
5	Northern South America	Aruba, Colombia, French Guiana, Grenada, Guyana, , Suriname , Trinidad and Tobago, Venezuela
6	Southwest South America	Argentina, Bolivia, Chile, Ecuador, Peru, Falkland Islands (Malvinas), Paraguay, Uruguay
7	Europe	Albania, Andorra, Austria, Belarus, Belgium, Belgium, Luxembourg, Bulgaria, Channel Islands, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Faroe Islands, Finland, France, Germany, Gibraltar, Greece, Greenland, Hungary, Iceland, Ireland, Isle of Man, Italy, Latvia, Liechtenstein, Lithuania, Luxembourg, Malta, Montenegro, Netherlands, Norway, Poland, Portugal, Republic of Moldova, Romania, Serbia, Slovakia, Slovenia, Spain, Sweden, United Kingdom, Ukraine
8	Northern Africa	Algeria, Cabo Verde, Chad, Côte d'Ivoire, Djibouti, Egypt, Eritrea, Ethiopia, Ethiopia PDR, Gambia, Guinea, Guinea-Bissau, Libya, Mali, Mauritania, Morocco, Saint Helena Ascension and Tristan da Cunha, Sao Tome and Principe, Senegal, Somalia, Sudan former, Tunisia, Western Sahara
9	Equatorial Africa	Benin, Burkina Faso, Burundi, Cameroon, Central African Republic, Congo, Democratic Republic of the Congo, Equatorial Guinea, Gabon, Ghana, Liberia, Nigeria, Rwanda, Sierra Leone, Togo, Uganda, United Republic of Tanzania,
10	Southern Africa	Angola, Botswana, Comoros, Lesotho, Madagascar, Malawi, Mauritius, Mayotte, Mozambique, Namibia, Reunion, Seychelles, South Africa, Swaziland, Zambia, Zimbabwe
11	Russia	Russian federation
12	Central Asia	Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, Uzbekistan, Mongolia,
13	Middle East	Armenia, Azerbaijan, Bahrain, People's Republic of Georgia, Iran, Iraq, Israel, Jordan, Kuwait, Lebanon, Occupied Palestinian Territory, Oman, Qatar, Saudi Arabia, Syrian Arab Republic, Turkey, United Arab Emirates, Yemen
14	China	China mainland, Macao, Hong Kong, Taiwan
15	Korea and Japan	Japan, Korea, Republic of Korea
16	South Asia	Afghanistan, Bangladesh, Bhutan, India, Nepal, Pakistan, Sri Lanka
17	South East Asia	Brunei Darussalam, Cambodia, Guam, Indonesia Kiribati, Lao People's Democratic Republic, Malaysia, Maldives, Marshall Islands, Myanmar, Nauru, Northern Mariana Islands, Palau, Philippines, Singapore, Solomon Islands, Thailand, Timor-Leste, Tokelau, Viet Nam
18	Oceania	American Samoa, Australia, Cook Islands, Fiji, French Polynesia, New Caledonia, New Zealand, Niue, Norfolk Island, Pacific Islands Trust Territory, Papua New Guinea, Pitcairn Islands, Samoa, Tonga, Tuvalu, Vanuatu, Wallis and Futuna Islands

Table S2 Assignment of the inventory specific sectors to GCP sub- and main categories

ESSD Main Category	ESSD Subcategory	EDGARv4.3.2	GAINS by-country	GAINS gridded	CEDS	USEPA
