THE IITM EARTH SYSTEM MODEL

Transformation of a Seasonal Prediction Model to a Long-Term Climate Model

BY P. SWAPNA, M. K. ROXY, K. APARNA, K. KULKARNI, A. G. PRAJEESH, K. ASHOK, R. KRISHNAN, S. MOORTHI, A. KUMAR, AND B. N. GOSWAMI

This work documents the fidelity of the newly developed Indian Institute of Tropical Meteorology climate model simulations and demonstrates its suitability to address the climate variability and change issues relevant to the South Asian monsoon.

The Indian Ministry of Earth Sciences and the National Oceanic and Atmospheric Administration (NOAA) entered into a formal agreement to collaborate on the implementation of the National Centers for Environmental Prediction (NCEP) weather and seasonal prediction system in India during 2011. As part of this collaboration, the India Meteorology Department (IMD) and National Centre for Medium Range Weather Forecasts (NCMRWF) implemented the high-resolution (T574, L64) atmospheric Global Forecast System (GFS) model with three-dimensional variational data assimilation (3DVAR) at IMD for short- and medium-range weather forecasts. Also, the coupled ocean–atmosphere model, Climate Forecast System version 2 (CFSv2), with a high-resolution atmosphere (T382, L64), was implemented for seasonal prediction at the Indian Institute of Tropical Meteorology (IITM). To address the long-term critical need in India for a climate model that would provide reliable future projections of Indian monsoon rainfall, IITM planned on building an Earth system model (ESM) based on the CFSv2 framework. Further, as part of the Monsoon Mission (see www.tropmet.res.in/), India is committed to improving the CFSv2 model for providing more skillful predictions of seasonal monsoon rainfall, which would also benefit the short- and medium-range predictions at IMD. Therefore, the extension of the seasonal prediction model to a long-term climate model would establish a seamless prediction system from weather time scales to seasonal

In final form 5 September 2014

and decadal time scales in India. In this paper, we describe how the seasonal prediction model has been converted into a model suitable for long-term climate studies.

The NCEP CFS (Saha et al. 2006), the predecessor of the CFSv2, has been used to provide coupled ocean–atmospheric forecasts since 2004, demonstrating good skill in simulating and predicting El Niño–Southern Oscillation (ENSO) (Wang et al. 2005; Zhang et al. 2007) and the South Asian summer monsoon variability (Achuthavarier and Krishnamurthy 2010; Yang et al. 2008; Pattanaik and Kumar 2010; Chaudhari et al. 2013; Pokhrel et al. 2012, 2013). With substantial changes compared to CFSv1, the CFSv2 (Saha et al. 2014) demonstrated better prediction skill for ENSO, the tropical Atlantic sea surface temperatures (SST), global land precipitation, surface air temperature, and the Madden–Julian oscillation (Yuan et al. 2011; Weaver et al. 2011; Jiang et al. 2013; Hu et al. 2013). Importantly, exhaustive hindcast experiments on seasonal and extended time scales carried out at IITM demonstrated that the CFSv2 model was one of the few models that predicted the general distribution of Indian summer monsoon rainfall during June–September (henceforth ISMR) and its intraseasonal and interannual variability with statistically significant skill (Roxy et al. 2012; Chaudhari et al. 2013).

To address issues related to longer time-scale climate variability, beyond the seasonal time scale, a climate model needs to simulate the observed mean climate reasonably well. Moreover, for a region like South Asia, a realistic simulation of the climatology and variability of the ISM and the drivers of its variability is imperative. Equally important is the ability to replicate the observed sensitivity in temperature to the increasing greenhouse gases (GHGs). However, despite its good seasonal prediction skill, several 100-yr simulations carried out at IITM demonstrated a cold bias in global mean temperature and a lack of the observed sensitivity to GHG increases in CFSv2, limiting its utility as a climate change model (e.g., Roxy et al. 2012). The model also exhibits a dry bias over the Indian subcontinent during the June–September (JJAS) monsoon season, along with colder-than-observed SSTs in the Arabian Sea (Roxy et al. 2012) and eastern tropical Indian Ocean (Chaudhari et al. 2013). Roxy et al. (2012) also noticed a systematic bias in the thickness of the mixed layer in the ocean component of CFSv2. While model systematic biases tend to affect the simulation of long-term mean climate as well as long-term projected trends, improved representation of oceanic processes is one approach to aid in minimizing systematic biases (see Semtner and Chervin 1992). For example, such an effort has substantially improved the simulation of many key climate features in GFDL CM2.5 (Delworth et al. 2012), a state-of-the-art model. These works provide motivation for the possible alleviation of systematic biases in the CFSv2 model through improved representation of ocean processes in the coupled model.

As a first step toward adapting the CFSv2 as an ESM, an ocean model with biogeochemistry, and a better physics scheme for improving the biases of the current ocean component in CFSv2, was incorporated. In this study, we document the formulation of the IITM-Earth System Model version 1 (IITM-ESMv1), and discuss improvements in simulations of various important ocean–atmospheric processes and variability.

The paper is organized as follows. Section 2 describes the model configuration, coupling strategy, experimental design, and initialization details of the climate simulations. Section 3 presents a comparative assessment of the simulated annual mean climate, and biases therein, between the simulations of CFSv2 and ESMv1. Section 4 describes the fidelity of simulated ENSO and Pacific decadal oscillation (PDO) patterns, dominant modes of climate variability on interannual and decadal scales, and teleconnection of ENSO to ISM. The results are summarized in section 5.

BRIEF DESCRIPTION OF THE IITM-ESMv1.

The IITM-ESMv1 has been developed by replacing the Modular Ocean Model ocean component (MOM4p0; Griffies et al. 2004) of the CFSv2 with MOM4p1 (Griffies et al. 2009) and retaining the land and atmosphere components. MOM4p1 has better physics compared to MOM4p0, as well as an interactive ocean biogeochemistry (BGC) component (Dunne et al. 2012). The major differences between the ocean components of IITM-ESMv1 and CFSv2 are summarized in the online supplement to this paper (available at http://dx.doi.org/10.1175/BAMS-D-13-00276.2).

Ocean and sea ice components. The ocean component (MOM4p1) in IITM-ESMv1 is a hydrostatic model using Boussinesq approximation and has a rescaled geopotential vertical coordinate (Stacey et al. 1995; Adcroft and Campin 2004) for a more robust treatment of free surface undulations. Key physical parameterizations include a KPP surface boundary layer scheme similar to that of Large et al. (1994), which computes vertical diffusivity, vertical viscosity, and nonlocal transport as a function of the flow and surface forcing. Griffies et al. (2009) provide

a detailed description of the model equation, physics, dynamics, time-stepping schemes, and further subgrid-scale parameterizations.

The IITM-ESMv1 ocean model has 40 vertical levels from the surface to 4500 m, identical to that of the CFSv2. It has 27 levels in the upper 400 m of the water column in an attempt to capture surface boundary layer processes. Bottom topography is represented by the partial cell method described by Adcroft et al. (1997) and Pacanowski and Gnanadesikan (1998). Both the ocean and sea ice models use the Arakawa B grid (Arakawa and Lamb 1977). The zonal resolution is 0.5° and the meridional resolution is 0.25° between 10°S and 10°N, becoming gradually coarser through the tropics, up to 0.5° poleward of 30°S and 30°N. The use of the Murray (1996) bipolar grid facilitates the removal of the coordinate singularity from the Arctic Ocean domain.

The sea ice component of IITM-ESMv1 is the Geophysical Fluid Dynamics Laboratory (GFDL) Sea Ice Simulator (SIS; Delworth et al. 2006; Winton 2000), which is an interactive dynamical sea ice model with three vertical layers, one snow and two ice, as well as five ice thickness categories.

Atmosphere and land components. The atmospheric component of IITM-ESMv1 is based on the NCEP GFS model and has a spectral triangular truncation of 126 waves (T126) in the horizontal (~0.9° grid) and finite differencing in the vertical with 64 sigma-pressure hybrid layers. It employs the simplified Arakawa–Schubert convection scheme, with cumulus momentum mixing. The land surface model (LSM) is the Noah LSM, with four layers (Ek et al. 2003), as in CFSv2. Further details can be found in Saha et al. (2010).

Coupling and initialization. The component models pass fluxes across their interfaces through an exchange grid system, which enforces the conservation of energy, mass, and tracers. The atmosphere, land, and sea ice exchange quantities such as heat and momentum fluxes every 10 min, with no flux adjustment or correction. The ocean tracer and atmosphere–ocean coupling time step is 30 min. The individual model components were initialized with 1 December 2009 initial conditions derived from the NCEP CFS reanalysis. The model has been integrated forward for a 100-yr period without any changes in radiative forcing. Importantly, the biogeochemistry and ecosystem modules were switched off to facilitate a comparison of the simulated climate statistics with those from the CFSv2. For convenience, we refer to this simulation as the ESMv1 run. For comparison, we utilize the results from a 100-yr run we carried out earlier with the CFSv2, which also started with the same set of initial conditions. Unless specified, the last 50 yr of the simulations from both models are used for the comparison.

Observation-based datasets used for evaluating the simulations. For the evaluation of the model simulations, we use the SST data from the 2009 version of the *World Ocean Atlas* (*WOA*; Locarnini et al. 2010) and density-based mixed layer depth data (de Boyer Montégut et al. 2004). We also use the Hadley Centre Sea Ice and Sea Surface Temperature dataset (HadISST1.1) (Rayner et al. 2003), gridded rainfall data from IMD (Rajeevan et al. 2006) for the period 1930–2010 and gridded monthly rainfall data from the Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI; Huffman et al. 2007) for 1998–2012, and the NCEP–National Center for Atmospheric Research (NCEP–NCAR) reanalysis (Kalnay et al. 1996) circulation fields for the period 1980–2010. Global surface air temperature anomalies are obtained from National Aeronautics and Space Administration (NASA) (Hansen et al. 2006), for the period of 2000–2010, and sea ice concentration data from HadISST (Rayner et al. 2003) for the period 1950–2010 are also utilized for the study.

The climatologies for the ESMv1 and the CFSv2 are computed for the last 50 yr of simulation. The simulated biases for any variable are computed by subtracting the observed value from the corresponding simulated value. The statistical significance of the bias is estimated based on a two-tailed Student's *t* test.

MEAN STATE IN ESMv1. *Annual mean surface temperature and SST.* The time evolution patterns of the global mean annual mean surface temperature and SST using ESMv1 and CFSv2 are examined (Fig. 1). During the initial 30 yr of the 100-yr run, the CFSv2 simulations undergo a rapid cooling from a global mean surface temperature (T_s) of 14.4°–13°C (Fig. 1a) and stay close to that range thereafter. This value is substantially less than the observed global T_s of 14.6°C (Hansen et al. 2006), indicating a bias of at least 1.6°C in the simulated global surface temperature. However, the initial cooling of simulated T_s by the ESMv1 is nearly about 0.6°C (Fig. 1a), and the T_s remains around 14.2°C thereafter. Importantly, the drift in the SST simulated by the ESMv1, averaged globally or in the tropics, is only about 0.4°C, as compared to an SST bias of 1.4°C in CFSv2 (Figs. 1b and 1c).

The spatial map of the annual mean SST bias (Fig. 2) indicates that the ESMv1 captures observed features well, on par with several other state-of-the-art coupled models (figure not shown). The spatial map of SST bias, computed as the difference between the observed annual mean SST from that of the HadISST and over the last 50 yr of simulations is shown for ESMv1 and CFSv2 in Figs. 2b and 2c, respectively. The 10% level of statistical significance of the SST bias estimated based on a Student's *t* test is shown with contours in Fig. 2. The results confirm a significant reduction in cold bias in the tropics between 30°S and 30°N, also as evidenced by the RMSEs of 0.79 and 0.89 for the ESMv1and CFSv2, respectively. A similar reduction of the biases is seen in northern subtropical gyres. One of the potential reasons for the improved reduction in the cold bias in the regions of northern subtropical gyres in ESMv1 is the use of the parameterization for the effect of submesoscale mixed layer eddies (Fox-Kemper et al. 2011), which prevents mixed layer depths from becoming excessively deep [Hallberg (2003); see also Fig. 4a and discussion in the following section]. The improvements in ESMv1 have been further ascertained by comparing the simulations with the *WOA* (figures not shown).

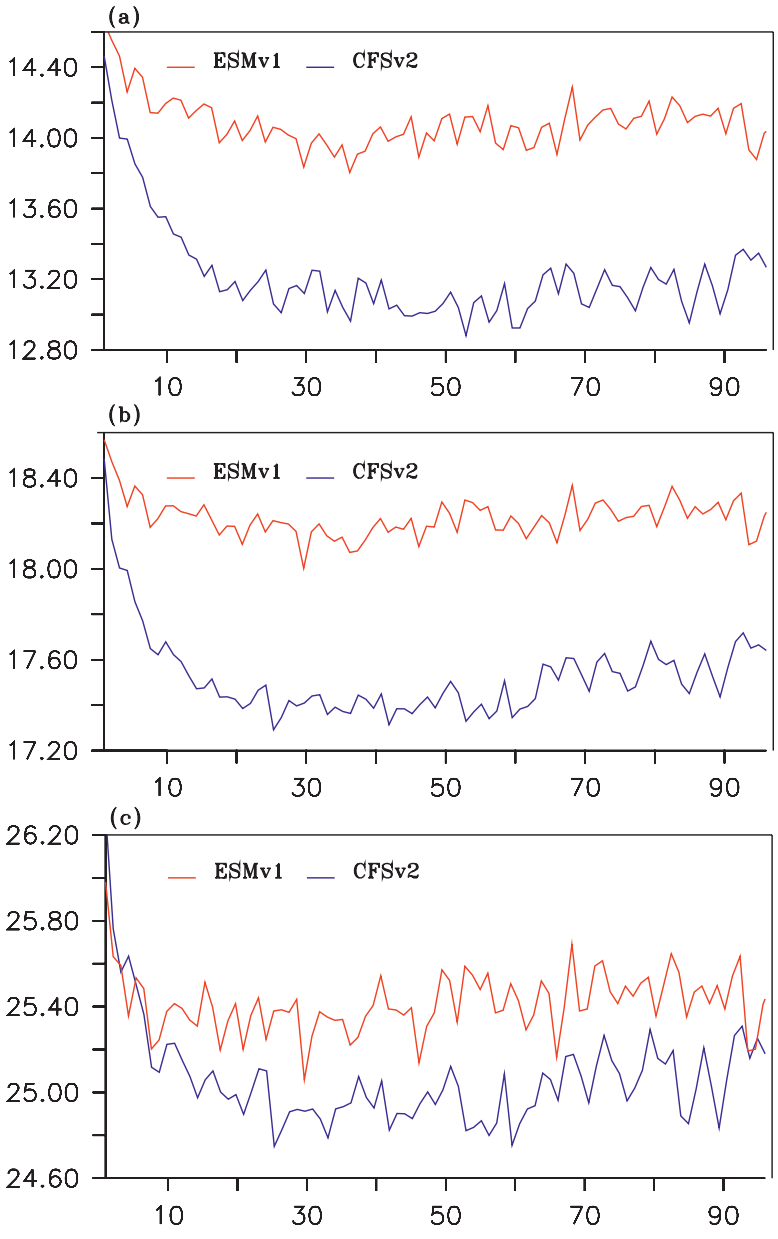

Fig. 1. Time-evolution of the globally averaged annual mean fields (°C) of (a) near-surface temperature, (b) SST, and (c) tropical SST (30°S–30°N). The ESMv1 (CFSv2) simulations are in red (blue). The corresponding annual mean observational values are 14.6°, 18.6°, and 26.1°C, respectively.

In both of the models, particularly CFSv2, however, the cold bias lingers in the North Atlantic Current east of Newfoundland, which is a region of very sharp gradients in SST. Small errors in the paths of ocean boundary currents can lead to such large SST biases (Griffies et al. 2011). While there is a notable and a general improvement in the tropical SST simulation, the warm biases in the far-eastern Pacific cold tongue and in the Southern Ocean have increased. We also note that warm biases are found in the Southern Ocean and in the upwelling region off the western coast of South America (Figs. 2b and 2c) in both the models, particularly in the ESMv1. The simulated warm bias in the Southern Ocean in ESMv1 is higher compared to in CFSv2 and is due to the weaker-than-observed simulated lower-level zonal winds (figure not shown). A recomputation of the SST biases, after removing the mean global SST (figure not shown), indicates that the difference between ESMv1 and CFSv2 is mainly reflected in the mean, and the spatial patterns of both ESMv1 and CFSv2 are nearly the same, with a significantly high pattern correlation ($r = 0.9$), implying that the large-scale features in both the models remains the same. We note that most of the phase 5 of the Coupled Model

Intercomparison Project (CMIP5) models exhibit similar biases with weaker-than-observed zonal winds in the Southern Ocean region (e.g., Fig. 5; Lee and Wang 2014).

Mean precipitation. The distributions of boreal summer monsoon (June–September) precipitation bias from ESMv1 and CFSv2 are shown in Fig. 3. The 10% level of statistical significance of the precipitation bias estimated based on a Student's *t* test is shown with contours in Fig. 3. Both CFSv2 and ESMv1 reproduce the observed precipitation patterns reasonably well, though they show larger-than-observed precipitation in the tropical western and eastern Pacific and the South Pacific convergence zone. However, there is improvement in the oceanic precipitation in ESMv1 in comparison with CFSv2, with a reduction in excess oceanic precipitation over the equatorial Maritime Continent region, the eastern equatorial Indian Ocean, and the western tropical Pacific Ocean, as compared to CFSv2.

Notwithstanding the improved SSTs in the tropical and northern Indian Ocean, the ESMv1 simulation also depicts a dry bias over India (Fig. 3b). In terms of interannual variability of the ISMR, the ESMv1 shows a climatological precipitation rate of 4.3 mm day^{-1} with a standard deviation of 0.53 mm day^{-1}, giving a coefficient of variation (the variability in relation to the observed mean) of 9%. The corresponding statistics for the observations are 6 mm day^{-1}, 0.48 mm day^{-1}, and 8%, respectively. These results suggest a moderate improvement in the interannual variability of the land precipitation with respect to CFSv2, for which corresponding values are 4 mm day^{-1}, 0.5 mm day^{-1}, and 7.5%, respectively. The ESMv1 also shows slight improvement in terms of intensity and propagation characteristics of monsoon intraseasonal oscillation (figure not shown).

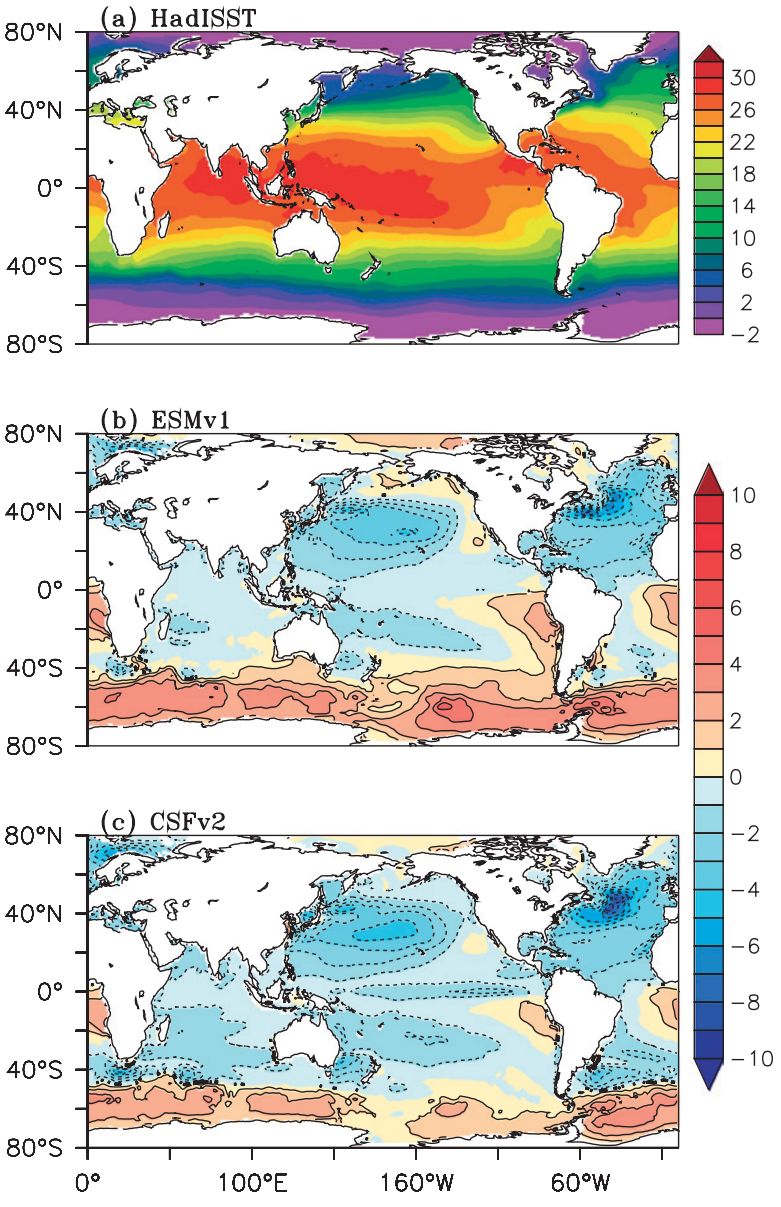

Fig. 2. (a) Spatial distribution of annual mean SST (°C) from HadISST and the biases for (b) ESMv1 and (c) CFSv2. The contours represent the 10% level of the statistical significance based on a Student's t test. The rms errors for the ESMv1 are 1.1° (global) and 0.79°C (30°S–30°N) and for the CFSv2 are 1.1° (global) and 0.89°C (30°S–30°N).

Ocean mixed layer and subsurface characteristics. One major difference between the ESMv1 and CFSv2 models is that the former employs Simmons et al.'s (2004) scheme for interior mixing along with mixed layer restratification by the submesoscale eddies (Fox-Kemper et al. 2008, 2011), as compared to the prescribed vertical diffusivity (Bryan and Lewis 1979) in the latter. To diagnose the role of such differences, we compare the simulated bias in annual mean ocean mixed layer depth (MLD) with respect to the observations (Fig. 4).

In general, the bias in the annual mean MLD is larger for CFSv2 (Fig. 4b) compared to ESMv1

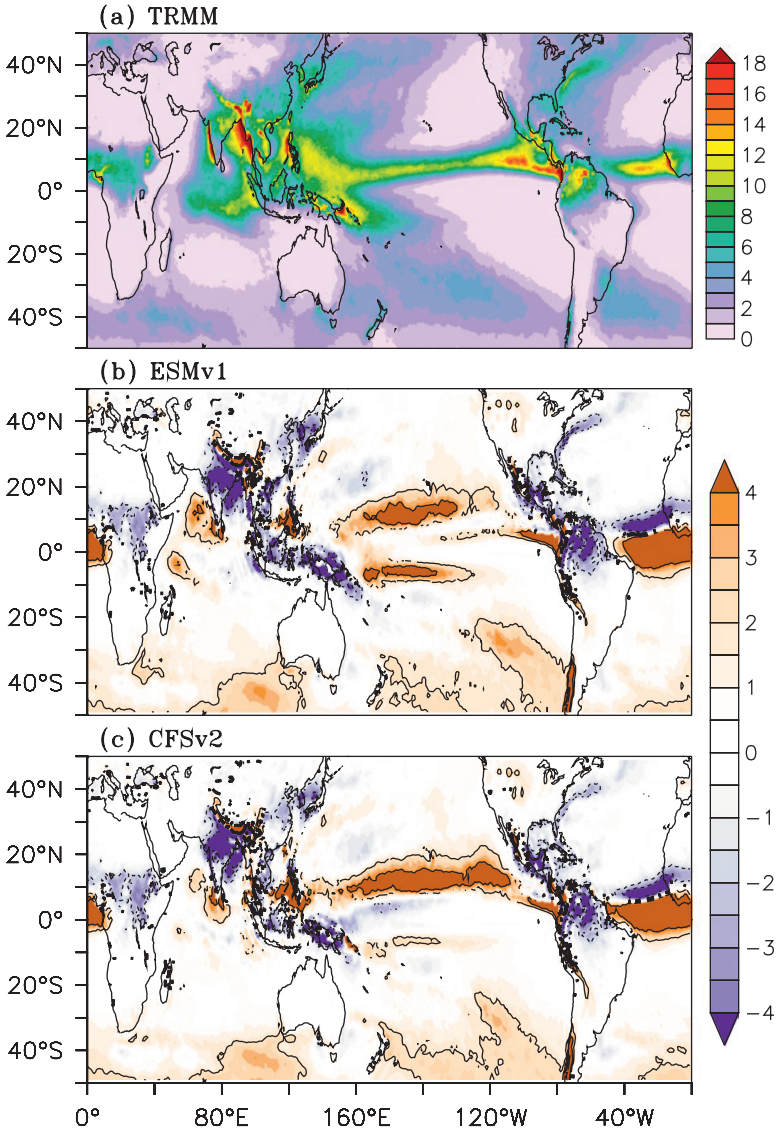

Fig. 3. Spatial map of mean summer monsoon precipitation (JJAS; mm day^{-1}) from the (a) TRMM and the biases for (b) ESMv1 and (c) CFSv2. The contours represent the 10% level of statistical significance based on a Student's *t* test.

(Fig. 4a). Significant improvement is seen in the tropical oceans, especially in the Arabian Sea and Bay of Bengal in the ESMv1 simulations. The 10% level of statistical significance of the MLD bias estimated based on a Student's *t* test is shown with contours in Fig. 4. Notably, Roxy et al. (2012) found that large biases of MLD in CFSv2 in the Arabian Sea during the summer monsoon season lead to an exaggerated SST–precipitation relationship. Indeed, improvements in the ESMv1-simulated MLD and SST also reflect an improvement in the precipitation in the tropics (Fig. 3). We note, however, a deeper-than-observed MLD in the region of northern subtropical gyres, as well as shoaling in the southern ocean in simulations by both models (Figs. 4a and 4b). The Southern Ocean shoaling is relatively larger in the ESMv1 simulation and consistent with the warm SST bias over the region (Fig. 2b). Our subsurface analysis shows that the warmer temperatures extend deeper in CFSv2 than in *WOA*, and ESMv1, as shown by the position of the 4°C isotherm in the zonally averaged vertical profiles of temperature (Figs. 4c–e). This is also seen in all three major individual ocean basins (see Fig. S1 in the online supplement to this article). This implies that pumping of heat away from the surface into deeper layers of the ocean takes place in the CFSv2, resulting in the cooling at the surface and warming of the ocean below.

DOMINANT PACIFIC MODES OF VARIABILITY AND INTERACTIONS WITH INDIAN SUMMER MONSOON. The Pacific Ocean exhibits substantial temporal and spatial variability. The large size of the basin facilitates unique atmosphere–ocean interannual coupled variability in the tropics, which is manifested as the El Niño–Southern Oscillation (ENSO; Rasmusson and Carpenter 1983). ENSO affects global climate and weather conditions such as droughts and floods (Ropelewski and Halpert 1987; Trenberth et al. 1998; Wallace et al. 1998; Ashok et al. 2007) and has a significant impact on the Asian summer monsoon (Sikka 1980; Webster et al. 1998; Wallace et al. 1998; Kumar et al. 1999; Krishnamurthy and Goswami 2000; Lau and Nath 2000; Ashok et al. 2004; Shukla 1995; Keshavamurty 1982). In this section, we evaluate the fidelity of the simulated ENSO and its interaction with the Indian summer monsoon. We also focus our attention on the fidelity of the simulated Pacific decadal oscillation (PDO). We use the last 75 yr of ESMv1 and CFSv2 simulations and qualitatively compared them with statistics from the 75 yr (1935–2010) of HadISST data.

El Niño–Southern Oscillation (ENSO). The largest observed SST variability (Fig. 5a) is localized

across the central-eastern equatorial Pacific, and is predominantly associated with the canonical ENSO. The models qualitatively reproduce the basic pattern of the observed SST anomaly variability. The coefficient of variation (contours) in Fig. 5 indicates that the interannual variability is about 5% of the mean in the observations and is well captured in ESMv1. However, the simulated variance in CFSv2 is significantly weaker as compared to the observations (Fig. 5c). The ESMv1, on the other hand, performs better both in terms of the magnitude and the extension of the variance maxima from the east through the date line in the equatorial Pacific (Fig. 5b). In the CFSv2 simulations, the maximum variance is confined mostly to the eastern portion of the eastern equatorial Pacific. This is consistent with slightly flattened thermocline slope from the central to eastern equatorial Pacific in CFSv2 compared to ESMv1 (Fig. 5d). However, it is to be noted that the EMSv1 slightly overestimates the westward extension of the variance in comparison with the observations and CFSv2. The thermocline is also relatively shallow in the west and deeper in the east for ESMv1, showing less improvement with respect to CFSv2.

To illustrate the fidelity of the spatial pattern of interannual variability associated with ENSO, the gravest EOF pattern for boreal winter (December–February) SST anomalies over the Pacific from the HadISST data and that from two models are presented in Fig. 6. The horseshoe pattern in the Pacific associated with the observed ENSO variability, with unipolar loadings in the central and eastern equatorial Pacific, and oppositely signed loadings west of the date line (Fig. 6a) is qualitatively captured by both of the models (Figs. 6b and 6c). The 31.5% variance explained by the EOF1 from the ESMv1 is reasonably close to the corresponding value of 37% from the observations. The corresponding explained variance from the CFSv2 is slightly smaller, at 29.5%.

The time-mean global wavelet spectrum from a wavelet analysis on the observed PC1, which is associated with ENSO, shows a broad peak in the range of 2–7 yr, with maximum power at ~5 yr (Fig. 7d). Both models capture this broad peak reasonably well (Figs. 7e and 7f). The ESMv1 also exhibits a decadal modulation of interannual variability (Figs. 7b and 7e), similar to the observations (Fig. 7a). Though longer time series are required to adequately characterize the ENSO (Wittenberg 2009), many of the simulated ENSO events appear to be episodic, spanning a range of frequencies over the course of one or two events.

ENSO–monsoon relationship in the coupled simulations. The ENSO–monsoon teleconnection, to a good extent, depends on the Walker circulation to deliver the Pacific SST signal to the Indian Ocean and Indian

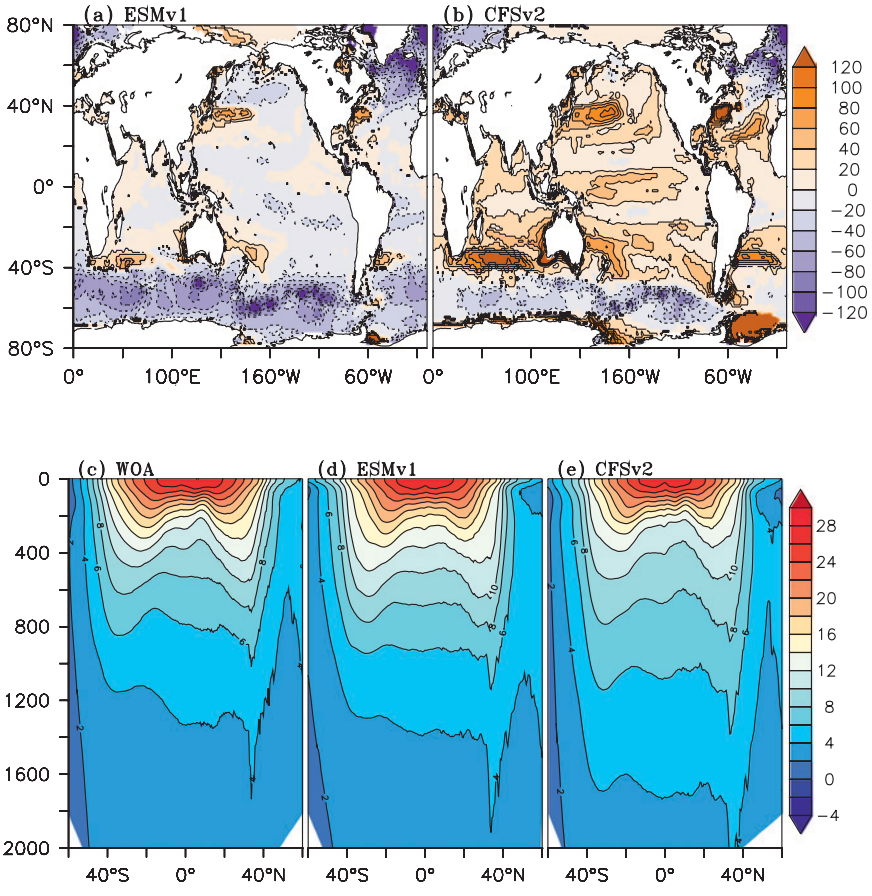

Fig. 4. Spatial maps of bias in annual mean mixed layer depth for (a) ESMv1 and (b) CFSv2. The model results are computed over the last 50 yr of the simulation. Biases are in meters. The contours represent the 10% level of the statistical significance based on a Student's *t* test. (c) Vertical distribution of the global ocean zonal mean temperature (°C) from *WOA*. (d),(e) As in (c), but for the ESMv1 and CFSv2, respectively.

land sector (Krishnamurti 1971; Shukla and Paolino 1983; Webster and Yang 1992). Hence, for a better representation of the Indian summer monsoon and its variability, a model should adequately reproduce the spatial, seasonal, interannual, and decadal aspects of the ENSO–monsoon connection.

We next compare the simulated ENSO–monsoon teleconnection in the climate simulations of ESMv1 and CFSv2 with one another and also with that from observations. Figure 8 shows the lead–lag correlation between the ISMR and the monthly Niño-3.4 index. This will give a general idea on the mean ENSO–monsoon relationship, though it may not hold for its interdecadal variability as the teleconnection changes on decadal time scales (e.g., Krishnamurthy and Goswami 2000; Kriplani and Kulkarni 1998). The observed simultaneous negative correlation (Shukla and Paolino 1983) between Niño-3.4 SST and ISMR, along with the peak correlation after the monsoon, is reasonably simulated by the ESMv1. However, in CFSv2 simulations, the negative correlations unrealistically start developing 12 months prior to the monsoon season. Further, the correlation peaks just at the beginning of the monsoon season, 2–3 months earlier than observed. In fact, this is a common problem among most of the climate models, including a significant number of CMIP3 and CMIP5 models (Jourdain et al. 2013; Achuthavarier et al. 2012).

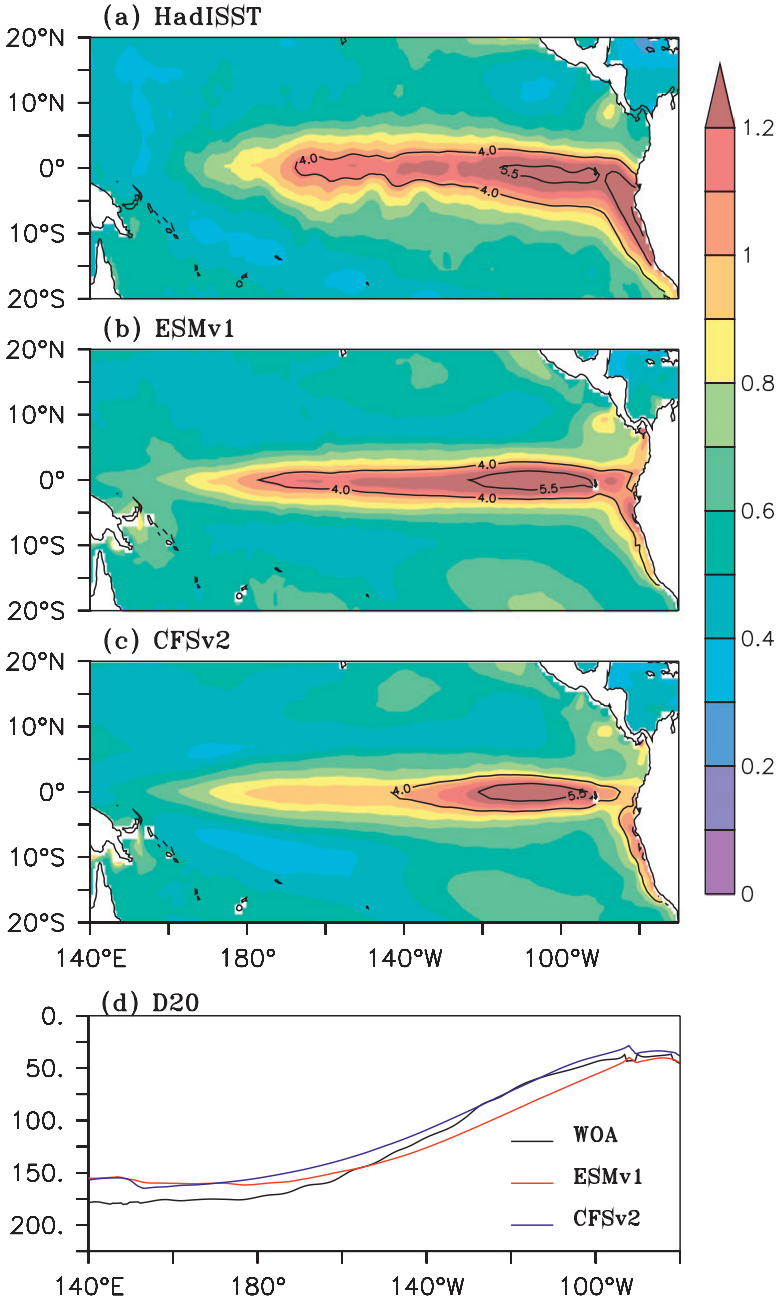

Fig. 5. Standard deviation of interannual SST anomalies (°C, shaded) for (a) HadISST, (b) ESMv1, and (c) CFSv2. The coefficients of variation (%) are overlaid as contours. (d) Depth of the 20°C isotherm (m) in the equatorial Pacific (5°S–5°N) for *WOA*, ESMv1, and CFS2.

To understand the spatial variability of rainfall associated with ENSO, we project the summer monsoon rainfall onto the PC1 obtained from the EOF analysis (Fig. 6) of the SST anomalies. The regression patterns from both of the simulations show (see Fig. S2) below normal rainfall over most of the Indian region, with an excess of rainfall over northeast India similar to the observed pattern (figure not shown) depicting the role of ENSO on the Indian summer monsoon cycle.

Pacific decadal oscillation (PDO). The PDO is the dominant mode of interdecadal variability in the Pacific characterized by warm SST anomalies near the equator and along the coast of North America and cool SST anomalies in the central North Pacific in its positive phase (Mantua et al. 1997; Zhang et al. 1997; Power et al. 1999). Studies have shown that the PDO-related interdecadal variability can modulate the ENSO

(Wang 1995) and the ENSO-related interannual variabilities. The PDO, with a periodicity of 20–30 yr, is shown to have significant impact on the climate around the Pacific Ocean and beyond (Krishnan and Sugi 2003; Power et al. 1999).

Following Mantua et al. (1997), we have performed an EOF analysis of detrended monthly SST anomalies over the domain 20°–60°N, 120°E–120°W for the last 75 yr of simulations to explore the simulated the PDO signal. For comparison, an EOF analysis is also performed on HadISST data for the period 1935–2010 over the same domain. The EOF1 results from the model and observations are shown in Fig. 9. The EOF1 pattern from HadISST data explains about 30.3% variance, with a unipolar signal in the central North Pacific surrounded by the oppositely phased loadings hugging the west coast of North America (Fig. 9a). This is the distinguishing feature of the warm phase of the PDO (e.g., Fig. 1; Krishnamurthy and Krishnamurthy 2014). The corresponding EOF1 from the ESMv1 (Fig. 9b) captures the pattern and associated explained variance reasonably well. On the other hand, the analogous EOF1 for the CFSv2 (Fig. 9c) explains only 24.4% of the total variance, and the spatial pattern shows relatively weak negative loadings in the North Pacific. This may be associated with the strong cold SST bias in the subtropical Pacific.

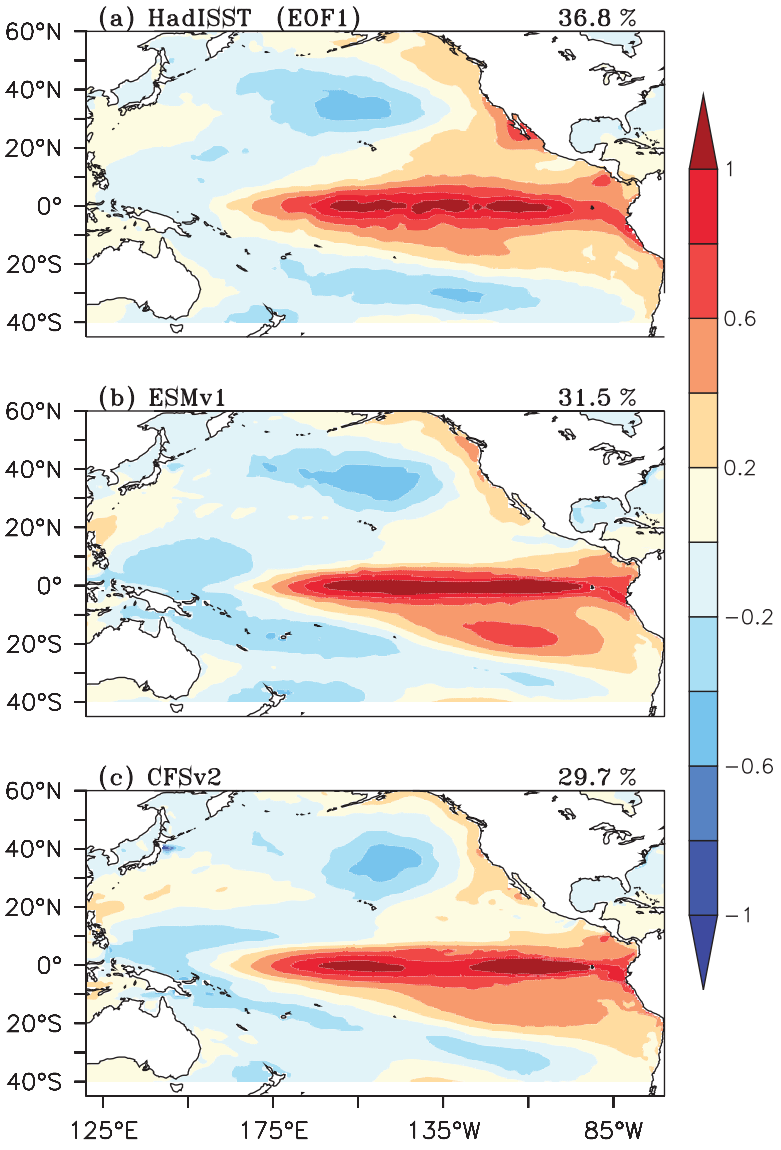

Fig. 6. The leading EOF pattern of boreal winter (December–February) SST anomalies (°C) in the Pacific for (a) HadISST data for the period 1935–2010 and the (b) ESMv1 and (c) CFSv2. The model results are computed over the last 75 yr of the simulation.

A wavelet power spectrum analysis on the observed PC1 (Fig. 9) indicates a dominant, and statistically significant, power in the 16–32-yr band (Figs. 10a and 10d). The ESMv1 successfully reproduces this dominant peak (Figs. 10b and 10e). However, in the CFSv2 simulations, it is weaker and not statistically significant (Figs. 10c and 10f).

Further, a regression of the December–February surface winds onto the PC1 indicates enhanced counterclockwise wind stress anomalies over the North Pacific (see Fig. S3a) associated with the PDO. Such an association is also seen in the simulations from the ESMv1 (Fig. S3b). The location of the anticyclonic winds and their magnitudes are well simulated. However, the counterclockwise surface circulation is weaker in the CFSv2 simulations (Fig. S3c) as compared to the observations and ESMv1 simulation. These, along with weaker-than-observed westerlies over the subtropical Pacific and the southeasterlies over the North American coast, are consistent with a weak PDO signal.

PDO and Indian summer monsoon. Krishnan and Sugi (2003) suggest that a warm phase of PDO can amplify the impact of El Niño, resulting in the weakening of the Indian summer monsoon.

Krishnamurthy and Krishnamurthy (2014) have shown that the PDO is associated with deficit rainfall anomalies mainly north of 18°N, with stronger anomalies in eastern central India. Indeed, a regression of the observed boreal summer monsoon rainfall (Rajeevan et al. 2006), for the period 1935–2010, onto the concurrent PDO index from the HadISST (Fig. 11a) conforms to these earlier observational works. The corresponding results from the simulations (Figs. 11b and 11c) are in qualitative agreement with Fig. 11a. However, the regression pattern from the CFSv2 simulation shows a slightly weaker-than-observed signal.

SUMMARY AND CONCLUSIONS. This paper documents the development of the first prototype of the IITM Earth System Model (ESMv1). Derived from the NCEP CFSv2, this model is being developed to be used in studies of the detection, attribution, and projections of climate change and its impact on the South Asian region. The effort particularly involved, as a first step toward the development of the IITM ESM, inclusion of an ocean biogeochemistry and ecosystem module and improved physics by replacing the ocean component of the CFSv2. Simulations of 100 yr were performed with the ESMv1and CFSv2, using the same initial conditions, and their results were compared. The new ocean formulation has led to a significant reduction in the cold atmospheric temperature bias (from 1.5° to 0.6°C) and SST bias as compared to that in the CFSv2. The improvement in SST is particularly prominent in the tropical Indian and Pacific Oceans. As a result, the precipitation over the tropical oceans has also improved considerably.

In addition, the simulations with IITM-ESMv1 also show improvements in the mean state and near-surface biases in the northern subtropical gyres as well, implying the role of ocean physics in the coupled climate simulations. Importantly, the model demonstrates a realistic global mean temperature and is reasonable sensitivity to the ambient CO_2, an essential prerequisite for a climate model to be used for climate change studies.

In terms of the spatial pattern and the periodicity, the ESMv1 simulations of climate variability are more realistic as compared to those of NCEP CFSv2. An example is the simulated PDO signal in CFSv2, which is much weaker than that

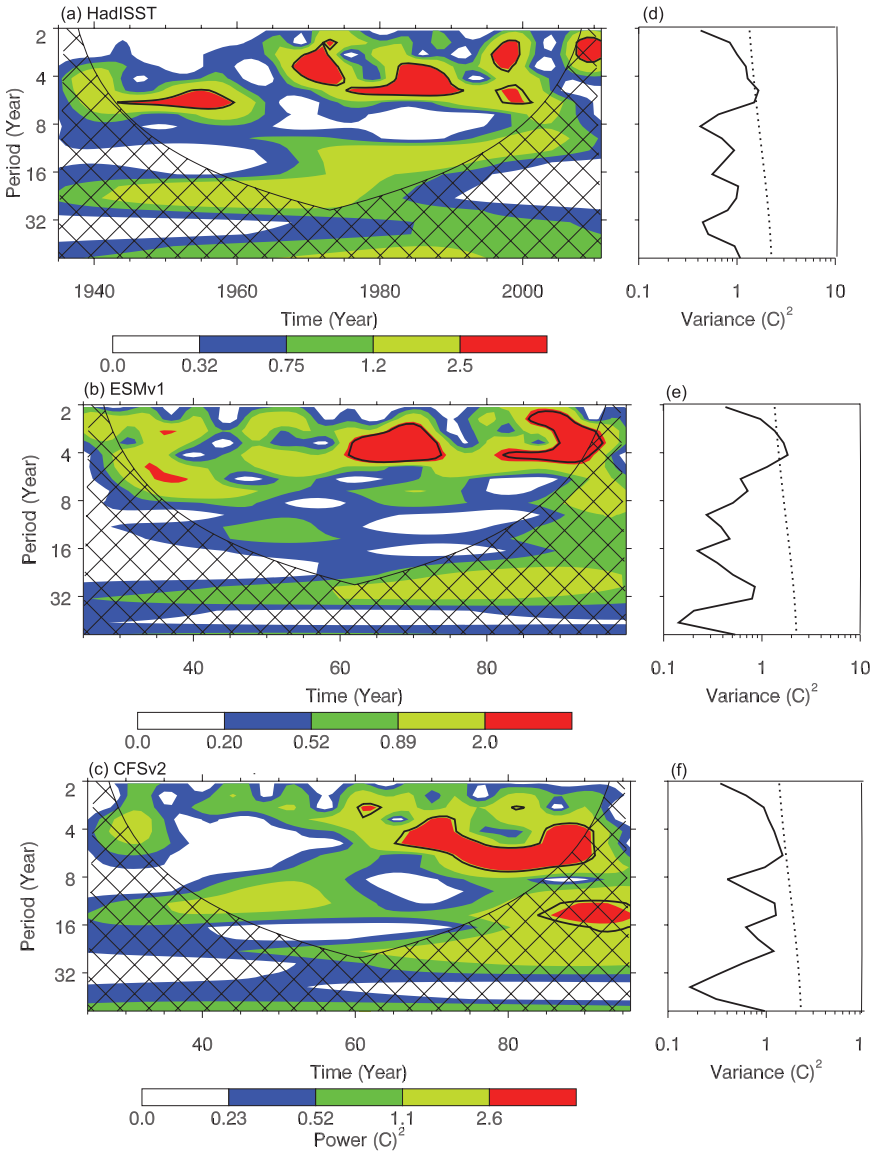

FIG. 7. Time series of wavelet power spectra of the gravest principal component from the EOF analysis of the Pacific winter SST (60°N–60°S, 120°E–80°W; see Fig. 6) for (a) HadISST, (b) ESMv1, and (c) CFSv2. The corresponding time-averaged power spectra are shown for (d) HadISST, (e) ESMv1, and (f) CFSv2.

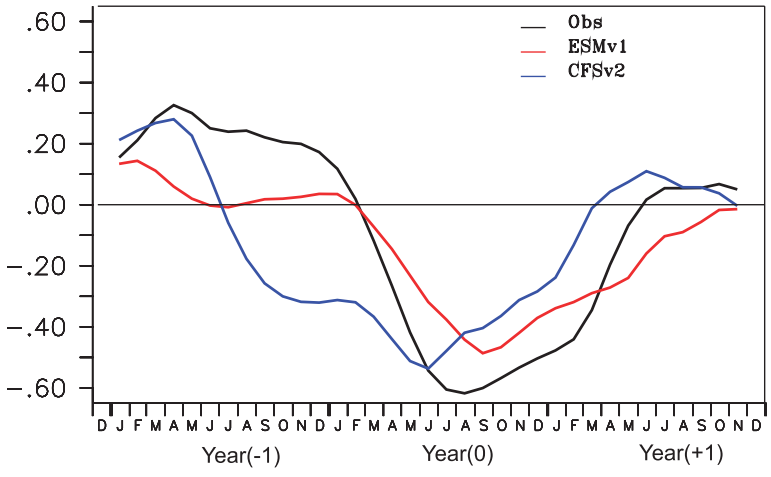
observed. Importantly, the ENSO–monsoon relationship in CFSv2 shows an unrealisticly strong, negative correlation maximum between the Indian summer monsoon rainfall and the Niño-3.4 index 6–9 months prior to the observations, which may result in unrealistic monsoon variations. This is a common problem in many of the CMIP5 models (Jourdain et al. 2013). However, the ESMv1 captures the observed concurrent negative simultaneous correlations between the monsoons and ENSO, as well as a reasonable lead–lag relationship between these two. All these features demonstrate the ability of the ESMv1 to capture the crucial monsoon–ENSO links, which are important in manifesting the interannual variability of the South Asian summer monsoon. A companion study (Shikha 2013) demonstrates that the ESMv1 also simulates a realistic evolution of the Indian Ocean dipole (Saji et al. 1999; Webster et al. 1999; Murtugudde 2000) and its variability (figure not shown).

A preliminary analysis of the simulated Atlantic meridional overturning circulation (AMOC) indicates (figure not shown) that the full AMOC has not been yet established in the simulation and warrants the extension of the current integration by a few more hundreds of years. Such a longer run



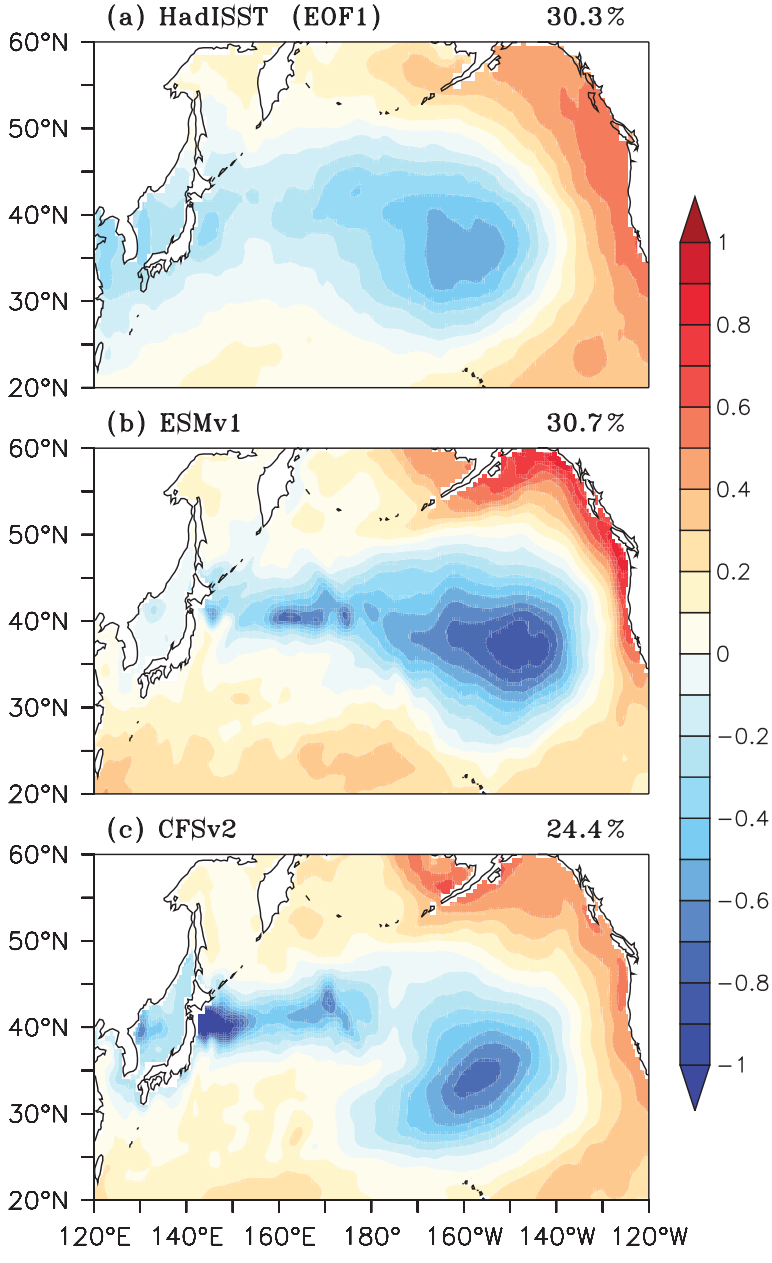


Fig. 8 (top). Lead–lag correlations between all Indian summer monsoon years derived from the IMD datasets (June–September) rainfall and the monthly Niño-3.4 index from the HadISST [for the 1935–2010 period (black line)], ESMv1 (red line), and CFSv2 (blue line). Note that the model results are computed over the last 75 yr of the simulation for comparison.

Fig. 9 (bottom). The leading EOF pattern of detrended monthly SST anomalies (°C) in the North Pacific (20°–60°N, 120°E–120°W) from (a) HadISST data for the period 1935–2010, (b) ESMv1, and (c) CFSv2. The model results are computed over the last 75 yr of the simulation.

will also result in more robust tropical climate statistics (e.g., Wittenberg 2009). We have also analyzed the distribution of sea ice concentration (Fig. S4) in the Northern Hemisphere from ESMv1 and CFSv2 for January–March (JFM) and June–September (JJAS). The Northern Hemisphere sea ice concentration in ESMv1 is comparable with HadISST data during JFM, the season when the sea ice coverage is largest in the Northern Hemisphere, but it is found to be lower than the observations during the boreal summer season (JJAS). Further, the Southern Hemisphere sea ice concentration is lower than observed (figure not shown) and more or less similar to that of the CFSv2. Importantly, Huang et al. (2015) note that the low sea ice concentration in CFSv2 has led to a weaker-than-observed AMOC in CFSv2, and improvement in sea ice concentration can be achieved by improving the sea ice albedo. Therefore, we plan to improve the sea ice parameters and also the coupling according to Huang et al. (2015) and extend the integration further to study the relevance of AMOC changes on the monsoon variability.

Even though the model's fidelity, in terms of the mean climate and seasonal cycle simulations, are on par with those of some other state-of-the-art models, the model still has a few limitations, such as a warm bias in the Southern Ocean region, which are common across a wide spectrum of CMIP5 models (Lee and Wang 2014). Another important issue is that the CFSv2 has a top-of-the-atmosphere energy imbalance of 6 W m^{-2}, which is fairly constant over a 100-yr simulation (figure not shown). A similar signal is also associated with ESMv1. Since the temperature has stabilized, the imbalance could be due to some unaccountable source of energy that is not tracked as part of the model integration, for example, because of the lack of dissipative heating of the turbulent kinetic energy (TKE; e.g., Fiedler 2000), or neglecting the radiative impact of precipitating hydrometeors (Waliser et al. 2011). Sun et al. (2010), Huang et al. (2007), and Hu et al. (2008) have pointed out that CFS has low cloud cover; this may be one of the possible reasons for the top-of-the-atmosphere energy imbalance in ESMv1. Within this context, it is worth noting that the annual average absorbed shortwave and outgoing

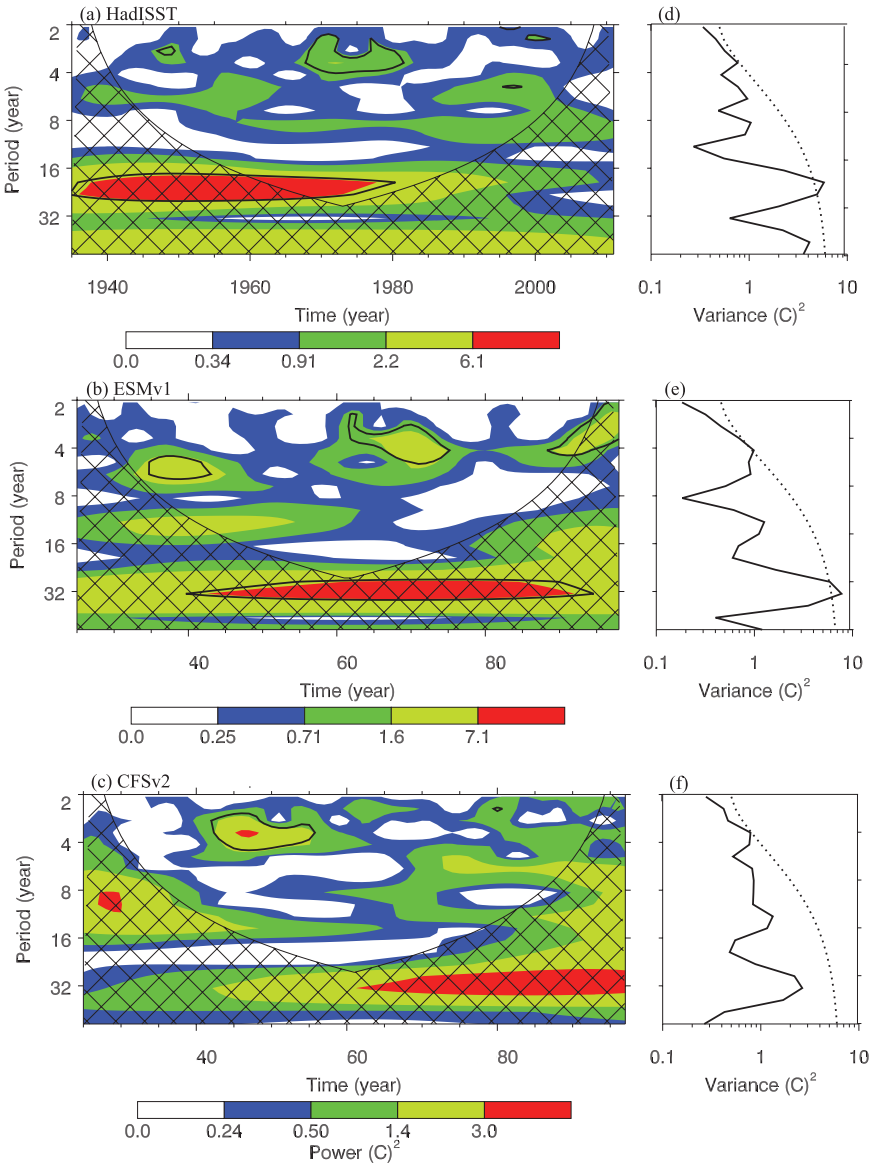

Fig. 10. Time series of wavelet power spectra of the gravest principal component from the EOF analysis of the North Pacific SST (20°–60°N, 120°E–120°W; see Fig. 9) for (a) HadISST, (b) ESMv1, and (c) CFSv2. The black contour is the 10% significance level. (d)–(f) The corresponding time-averaged spectra. The dashed line shows the 10% significance for the time-averaged power spectra.

longwave radiation values across the ITCZ regions for the ensemble average of CMIP3 GCMs were shown to have biases, as reported by Trenberth and Fasullo (2010). Trenberth and Fasullo (2010) also find that many of the CMIP3 models poorly simulate the energy budget in the Southern Hemisphere. This aspect needs further attention. Importantly, a recent study by Bombardi et al. (2015) shows that, despite such biases, retrospective decadal forecasts by the CFSv2 model show high predictive skill over the Indian, the western Pacific, and the Atlantic Oceans. Another issue that needs further attention is that despite an improvement in the oceanic precipitation, the dry bias over the Indian subcontinent associated with the CFSv2 simulations is still seen in the ESMv1 simulations as well. These issues will be addressed in the next version of the model. Significantly, a few recent sensitivity experiments carried out using the CFSv2 model (Hazra et al. 2015) suggest that improving the cloud microphysics will alleviate this problem substantially. In addition, parallel efforts are also working toward including an aerosol module in the ESM.

Summing up, the ESMv1 is a promising development for facilitating future projections relevant to South Asian climate, specifically those that envisage the next three to five decades in the future.

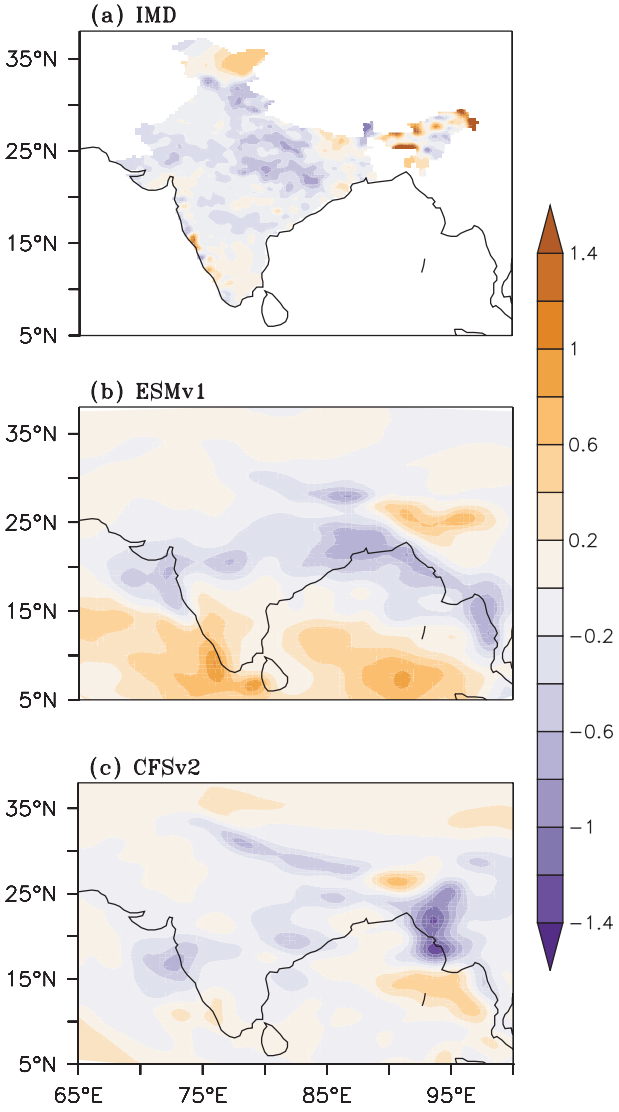

Fig. 11. Spatial map of JJAS rainfall anomalies (mm day^{-1}) regressed to the gravest principal component from the EOF analysis of the North Pacific (20°–60°N, 120°E–120°W; see Fig. 9) from (a) observations (for the period 1935–2010), (b) ESMv1, and (c) CFSv2. The model results are computed over the last 75 yr of the simulation.

ACKNOWLEDGMENTS. We thank the editor, Dr. Brian Etherton, for conducting the review process and also the three anonymous reviewers for the constructive comments. The authors acknowledge Drs. S. M. Griffies, V. Balaji, Xingren Wu, and R. Murtugudde for technical discussions and Ms. B. Preethi for her help in making the CFSv2 simulations. The IITM, including the CCCR, is part of the Ministry of Earth Sciences, government of India.

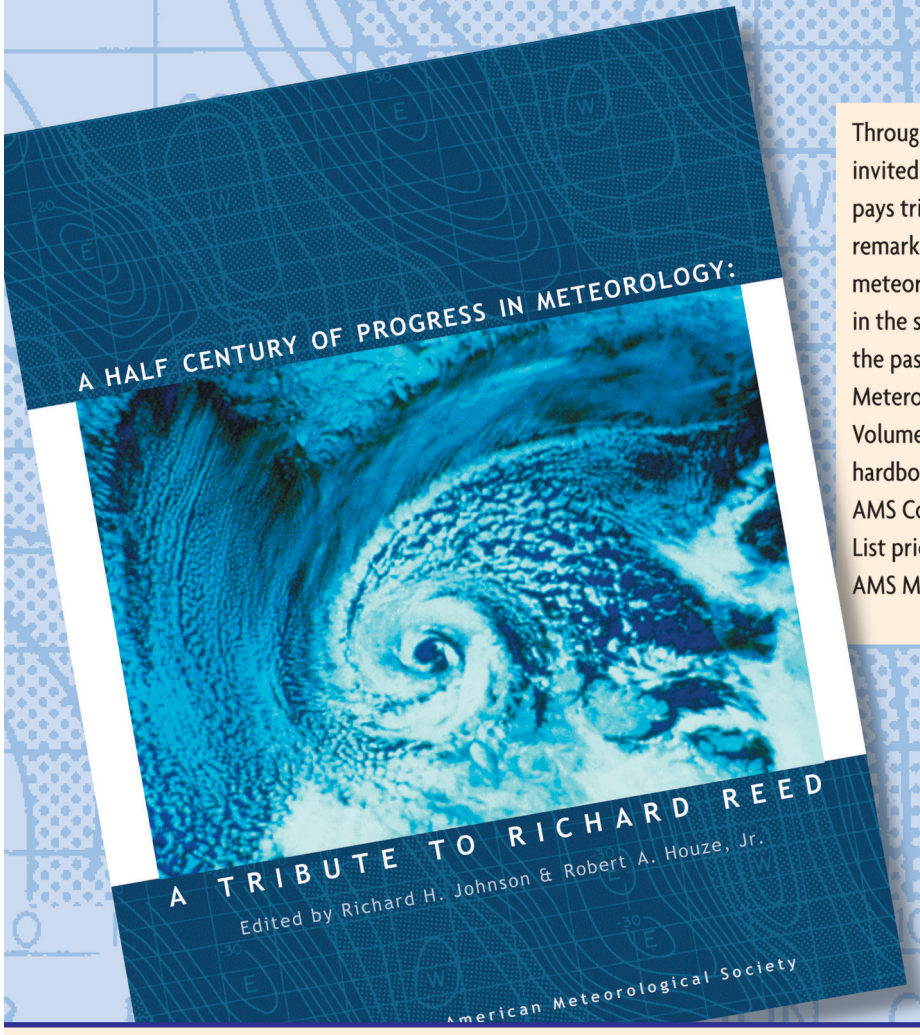
A Half Century of Progress in Meteorology: A Tribute to Richard Reed

edited by Richard H. Johnson and Robert A. Houze Jr.

with selections by: Lance F. Bosart Robert W. Burpee Anthony Hollingsworth James R. Holton Brian J. Hoskins Richard S. Lindzen John S. Perry Erik A. Rasmussen Adrian Simmons Pedro Viterbo



Through a series of reviews by invited experts, this monograph pays tribute to Richard Reed's remarkable contributions to meteorology and his leadership in the science community over the past 50 years. 2003. Meterological Monograph Series, Volume 31, Number 53; 139 pages, hardbound; ISBN 1-878220-58-6; AMS Code MM53.
List price: $80.00
AMS Member price: $60.00
