## Abstract

We present a performance assessment of the European Integrated Carbon Observing System (ICOS) atmospheric network for constraining European biogenic CO<sub>2</sub> fluxes (hereafter Net Ecosystem Exchange, NEE). The performance of the network is assessed in terms of uncertainty in the fluxes using a state-of-the-art mesoscale atmospheric inversion system assimilating hourly averages of atmospheric data to solve for NEE at 6 h and 0.5° resolution. The performance of the ICOS atmospheric network is also assessed in terms of uncertainty reduction compared to typical uncertainties in the flux estimates from ecosystem models that are used as prior information by the inversion. The uncertainty in inverted fluxes is computed for two typical periods representative of summer and winter conditions in July and in December 2007, respectively. These computations are based on a robust Observing System Simulation Experiments framework. We analyze the uncertainty in two-week mean NEE as a function of the spatial scale, with a focus on the model native grid scale (0.5°), the country scale and the European scale (including western Russia and Turkey). Several network configurations, going from 23 to 66 sites, and different configurations of the prior uncertainties and atmospheric model transport errors are tested in order to assess and compare the improvements that can be expected in the future from (1) the extension of the network, (2) improved prior information or (3) improved transport models. Assimilating data from 23 sites (a network comparable to present day capability) with the estimate of errors from the present prior information and transport models, the uncertainty reduction on two-week mean NEE should range between 20 and 50 % for 0.5° resolution grid cells in the best sampled area encompassing eastern France and western Germany. At the European scale, the prior uncertainty in two-week mean NEE is reduced by 50 % (66 %, down to ~ 43 TgC month<sup>-1</sup> (resp. 26 TgC month<sup>-1</sup>) in July (resp. December). Using a larger network of 66 stations, the prior uncertainty of NEE is reduced by the inversion by 64 % (down to ~ 33 TgC month<sup>-1</sup>) in July and by 79 % (down to ~ 15 TgC month<sup>-1</sup>) in December. When the results are integrated over the well-observed western Euro-

pean domain, the uncertainty reduction shows no seasonal contrast. The effect of decreasing the correlation length of the prior uncertainty, or of reducing the transport model errors compared to their present configuration (when conducting real-data inversion cases) can be larger than that of the extension of the measurement network in areas where the 23 stations observation network is the densest. We show that with a configuration of the ICOS atmospheric network containing 66 sites that can be expected on the long-term, the uncertainties in two-week mean NEE will be reduced by up to 50–80 % for countries like Finland, Germany, France and Spain, which could bring a significant improvement of (and at least a high complementarity to) our knowledge about NEE derived from biomass and soil carbon inventories at multi annual scales.

## 1 Introduction

Accurate information about the terrestrial biogenic CO<sub>2</sub> fluxes (hereafter Net Ecosystem Exchange – NEE) is needed at the regional scale to understand the drivers of the carbon cycle. Accounting for the natural fluxes in political agreements regarding the reduction of the CO<sub>2</sub> emissions requires their accurate quantification over administrative areas, and in particular over countries and smaller regional scales at which land management decisions can be implemented.

The atmospheric inversions, which exploit atmospheric CO<sub>2</sub> mole fraction measurements to infer information about surface CO<sub>2</sub> fluxes (Enting, 2002) are expected to deliver robust and objective quantification of NEE at high temporal and spatial resolution over continuous areas and time periods. Global atmospheric inversions have been widely used to document natural carbon sources and sinks (Gurney et al., 2002; Rodenbeck et al., 2003), although the spread of different studies, and thus, likely the uncertainty, remain large at the 1 month and continental scale (Peylin et al., 2013). Such large uncertainties are mainly due to the lack of observations over the continents or to the limited ability of global systems to account for dense observation networks in addition to errors in large-scale atmospheric transport models. However, with an increasing

number of continuous atmospheric CO<sub>2</sub> observations, primarily in North America and Europe, and with the development of regional inversion systems using high resolution mesoscale atmospheric transport models and solving for NEE at typical resolutions of 10 to 50 km (Lauvaux et al., 2008, 2012; Schuh et al., 2010; Broquet et al., 2011; Meesters et al., 2012), there is an increasing ability to constrain NEE at continental to regional scales.

This paper aims at studying the skill of a regional inversion in Europe, which is equipped with a relatively large number of ground-based atmospheric measurement stations, for estimating NEE at the continental and country scales, down to 0.5° resolution (which is the resolution of the transport model used in the inversion system). It also aims at assessing and comparing the benefits from the measurement network extensions and from future improvement in the inversion system. Such improvement can be anticipated either due to better atmospheric transport models or to the use of better flux estimates as the prior information that gets updated by the inversion based on the assimilation of atmospheric measurements.

Europe is a difficult application area for atmospheric inversion because of the very heterogeneous distribution of vegetation types, land use, and agricultural and industrial activities inside a relatively small domain, and, consequently, because of the need for solving for fluxes at high resolution. Furthermore, its complex terrain also requires a high resolution of the topography when modeling the atmospheric transport (Peters et al., 2010). However, the Integrated Carbon Observing System (ICOS) infrastructure is setting up a dense network of standardized, long-term, continuous and high precision atmospheric and flux measurements in Europe, with the aim of understanding the European carbon balance and monitoring the effectiveness of Greenhouse Gas (GHG) mitigation activities (<http://www.icos-infrastructure.eu/>). The atmospheric network is expected to increase from an initial configuration of around 23 stations (most existing today, hereafter ICOS23) up to around 60 stations in the near future (see ICOS Stakeholder handbook 2013 at [https://www.icos-ri.eu/file/61/download?token=wlyz4g2\\_](https://www.icos-ri.eu/file/61/download?token=wlyz4g2_)).

stations are relatively far from large urban areas. Therefore, in order to simulate the full amount of CO<sub>2</sub> in the atmosphere, the inversion uses a fixed estimate of the fossil fuel emissions (see below) without attempting at correcting it nor at accounting for uncertainties in these fluxes. The inversion also uses a fixed estimate of the CO<sub>2</sub> boundary conditions at the lateral and top boundaries of the regional modeling domain without attempting at correcting it or at accounting for uncertainties in these conditions. This follows the protocol from Broquet et al. (2011) which assumed that the error from the boundary conditions for the European domain is mainly a bias and which corrects for such a bias in a preliminary step that is independent to the subsequent application of the inversion. In this section we only summarize the main elements of the inversion system, starting with the theoretical framework, while the detailed description can be found in Broquet et al. (2011).

We define the control vector  $\mathbf{x}$  of the atmospheric inversion as the 6 h and 0.5° × 0.5° mean NEE and ocean fluxes. The atmospheric inversion seeks the mean  $\mathbf{x}_a$  and covariance matrix  $\mathbf{A}$  of the normal distribution  $N(\mathbf{x}_a, \mathbf{A})$  of the knowledge on  $\mathbf{x}$  based on (i) the atmospheric transport model, (ii) the prior knowledge  $\mathbf{x}_b$  of  $\mathbf{x}$ , (iii) the hourly mean atmospheric measurements  $\mathbf{y}$ , (iv and v) the covariances  $\mathbf{B}$  and  $\mathbf{R}$  of the distributions of the prior uncertainty and of the observation error assuming that these uncertainties are normal and unbiased (i.e., equal to  $N(0, \mathbf{B})$  and  $N(0, \mathbf{R})$  respectively), and (vi) a Bayesian relationship between these distributions. The observation error is the combination of all sources of misfit between the atmospheric transport model and the concentration measurements other than the prior uncertainty, in particular the measurement errors, the model transport, aggregation and representation errors, and the errors from the model inputs that are not controlled by the inversion.

With this theoretical framework,  $\mathbf{x}_a$  is the minimum of the quadratic cost function  $J(\mathbf{x})$  (Rodgers, 2000):

$$J(\mathbf{x}) = \frac{1}{2}(\mathbf{x} - \mathbf{x}_b)^T \mathbf{B}^{-1} (\mathbf{x} - \mathbf{x}_b) + \frac{1}{2}(H(\mathbf{x}) - \mathbf{y})^T \mathbf{R}^{-1} (H(\mathbf{x}) - \mathbf{y}) \quad (1)$$

of iterations and of inversion experiments. However, it has been checked (see below Sect. 2.2.2) that the convergence is sufficient so that this dependence should not be significant for the quantities of interest.

## 2.2.2 Practical set-up

### 5 Atmospheric transport model

In this study, the operator **H** is based on the CHIMERE mesoscale atmospheric transport model (Schmidt et al., 2001) forced with ECMWF winds. We use a configuration with a  $0.5^\circ \times 0.5^\circ$  horizontal grid and with 25  $\sigma$ -coordinate vertical levels starting from the surface and with a ceiling at  $\sim 500$  hPa. The spatial extent of the corresponding domain is described below in section. CHIMERE is an off-line transport model. Hourly mass-fluxes are provided by the analyses of the European Centre for Medium-Range Weather Forecasts (ECMWF). The relatively high vertical and horizontal resolutions of CHIMERE allow a good vertical discretization of the Planetary Boundary Layer (PBL; the first 14 levels are below 1500 m) along with a good representation of the orography and dynamics to match high frequency observations better than with global configuration whose typical horizontal resolution is  $\sim 3^\circ$  (Peylin et al., 2013).

### Spatial and temporal domains

In this study, we use the European domain shown in Fig. 1a which covers most of the European Union and some of Eastern Europe, with a land surface area of  $6.8 \times 10^6$  km<sup>2</sup>. Its southwest corner is at  $35^\circ$  N and  $15^\circ$  W, and its northeast corner is at  $70^\circ$  N and  $35^\circ$  E. Two temporal windows are considered, from 30 June to 20 July 2007 and from 2 to 22 of December 2007 (of almost three weeks each). The choice of those periods of three weeks is a tradeoff between widening the scope of the study and computational burden. The Monte Carlo-based flux uncertainty reduction calculations require large computing resources, while we test three different network configurations for two differ-

## Observation error covariance matrix

The observational error covariance matrix  $\mathbf{R}$  accounts for various sources of error when comparing the hourly data selected for assimilation and their simulation which are not controlled by the inversion: measurement error, aggregation error, atmospheric model representativeness and transport error (as explained previously, uncertainties in the anthropogenic emissions and in the boundary conditions are assumed to be negligible). The first two terms are negligible compared to the model representativeness and transport error due to the high measurement standard and to solving for the fluxes at 6 h and 0.5° resolution during the inversion, respectively.

Broquet et al. (2011) derived a quantitative estimation of the model error (depending on the station height) including transport and representativeness errors based on comparisons between simulations and measurements of CO<sub>2</sub> and <sup>222</sup>Rn. Broquet et al. (2013) resumed it to provide season-dependent estimates which are used here. The model error is much higher during the winter than that during the summer. It is given for each site in Table A1 for the two months (July, December) considered in this study. We assume that the errors for two different sites are independent and that they do not bear temporal autocorrelations. Thus, the observation error covariance matrix  $\mathbf{R}$  is set diagonal. The resulting budget of observation errors at daily to monthly resolution seems reliable (Broquet et al., 2011, 2013) and, therefore, this assumption does not seem to need to be balanced by an artificial increase of the observation errors for hourly averages.

## Minimization and number of members in the Monte Carlo ensembles

We use 12 iterations of minimization for each variational inversion of the Monte Carlo ensemble experiments. This number is similar to that from Broquet et al. (2011) where they considered a longer time period for the inversions but far smaller observation networks and a smaller inversion domain, which reduces the dimensions of the minimization problem. However, here, 12 iterations were still found to be sufficient for converging

Interactive Discussion

transport model improvement on the posterior flux uncertainties by reducing the default observation error SDs in  $\mathbf{R}$  by a factor of two. This factor roughly corresponds to the improvement of the misfits between the model and actual measurement at the site TRN (see Fig. 1 for its location), that was observed when bringing CHIMERE from the current 0.5° resolution down to a 2 km resolution using the configuration presented in Bréon et al. (2014). The underlying assumption would be that  $\sim 1$  km horizontal resolution atmospheric transport models could be used for inversions at the European scale in the near future. Hereafter, we denote by  $\mathbf{R}_{\text{ref}}$  the reference configuration of  $\mathbf{R}$  and by  $\mathbf{R}_{\text{red}}$  the one corresponding to reduced SDs.

### Test of the sensitivity to the prior uncertainty

The test of the sensitivity of the inversion system to the prior uncertainty is focused on that of the sensitivity to the spatial correlation length in  $\mathbf{B}$  (Gerbig et al., 2006) (which impacts the budget of uncertainty over large regions). The possible use of better prior flux fields based on the merging of both estimates from vegetation models and from large scale inventories (such as forest and agricultural inventories) can be expected to generate smaller-scale uncertainties than when using vegetation models while it is not obvious that local uncertainties would be decreased when adding information from inventories (since inventories only measure long term integrated NEE). Therefore, we tested the impact of reducing the spatial correlation length for the prior uncertainty in NEE from 250 to 150 km, denoting hereafter the corresponding configurations for the  $\mathbf{B}$  matrix:  $\mathbf{B}_{250}$  and  $\mathbf{B}_{150}$  respectively.

## 3 Results and discussion

### 3.1 Assessment of the performance of the actual network and system

In this section, the performance of the inversion relying on the default configuration and on the ICOS23 initial state network (i.e., the reference inversion) is analyzed as a func-

tion of the spatial scale, highlighting the main patterns of the uncertainty reduction obtained at the pixel scale to the European scale.

### 3.1.1 Analysis at the model grid scale

Figure 2a and b shows the uncertainty reduction for estimates of two-week average NEE at  $0.5^\circ$  resolution in July and December, respectively. This grid-scale uncertainty reduction reaches 65% for areas in the vicinity of the ICOS sites and decreases smoothly with distance away from measurement sites. For most of the area around eastern France – western Germany, this grid – scale uncertainty reduction ranges from 35 to 50% for July and from 20 to 40% for December. This stems from the combination of the dense observation network over that region, and from the 250 km correlation scale for the prior uncertainties, which spreads the error reduction beyond the immediate vicinity of each station where near field fluxes have a large influence on the mixing ratio at this station (Bocquet, 2005). For other parts of Europe that are not well sampled by ICOS, significant uncertainty reductions are generally seen around each site but there are large areas where the inversion has no impact at the grid scale: Scandinavian countries, the eastern part of Germany, Poland, south of the Iberian Peninsula and almost all of Eastern Europe.

The spatial structure of the uncertainty reduction and the underlying spatial extrapolation from a site is a complex combination of transport influence and of the structure of the prior uncertainty. Due to varying transport conditions, SD of the prior uncertainty at the grid scale (which is larger in summer, see below the comments on Fig. 3), and observation error (which is larger in winter), the spatial distribution of uncertainty reduction is found to vary from summer to winter. Because of the variation of prior and observation uncertainties between July and December, there is generally a larger uncertainty reduction in July (especially in Western Europe). But variations in meteorology alter (limiting or enhancing) this general behavior. The lower vertical mixing (which strengthens the sensitivity of the near ground measurements to the local fluxes) partly balances the higher observation error in December and the range of local uncertainty

Interactive Discussion

during July. It is larger than 50 % for a large majority of the countries in Western Europe and Scandinavia both in July and December.

The smallest uncertainty reduction applies to southeastern European countries where it can be smaller than 10 % (e.g., for Greece in July) indicating that the presence of stations very close to or within a given country is a requisite for bringing significant improvement to the estimates of NEE in this country. In general, the differences of the inversion skill between July and December look consistent with what has been analyzed at the pixel scale. In particular the uncertainty reduction is higher in July for western countries but higher in December for eastern countries.

### 3.1.3 Analysis at the European scale

Table 1 shows that the uncertainty in two-week-mean NEE in July averaged over the full European domain ( $6.8 \times 10^6 \text{ km}^2$  of land surface) is reduced by the inversion by 50 % down to a value of  $\sim 43 \text{ TgC month}^{-1}$  (see Table 1 for details) using the default configuration. The uncertainty reduction for December is 66 %, resulting in a posterior uncertainty of  $\sim 26 \text{ TgC month}^{-1}$ . The uncertainty reduction for the whole European domain is thus higher in December than in July. More precisely, while easterly winds in December strongly favor this period in terms of uncertainty reduction in Eastern Europe, the uncertainty reduction for NEE averaged over the reduced western European domain defined in Fig. 1c does not vary significantly with the season (66 and 64 % for July and December respectively). This lack of seasonal variation of the uncertainty reduction at the scale of the western European domain (where most of the ICOS23 stations are located) seems to contrast with the grid-scale and national scales estimations in this domain which indicated that the uncertainty reduction is generally significantly higher during summer than during winter. This contrast will be analyzed and interpreted in the following Sect. 3.1.4.

The values for the posterior uncertainty aggregated over Europe obtained with our reference configuration of the inversion are consistent with posterior uncertainties at the annual scale from the Carbon Tracker-EU system (CT-EU, Peters et al., 2010;

http://www.carbontracker.eu) who assimilated data from 15 continuous observing sites in Europe (corresponding to a network very similar to the ICOS23 geographical configuration and with a lot of sites included in ICOS23). By assuming no error temporal correlations between uncertainties from month to month but a full temporal autocorrelation of the uncertainties within one month from a two week period to the next one (which roughly reflects the 1 month temporal autocorrelation used for the prior uncertainty in this study), such estimate, when scaled down on our study domain, yields uncertainties of  $\sim 74 \text{ TgC month}^{-1}$  for monthly fluxes.

### 3.1.4 Analysis of the variations of the uncertainty as a function of the spatial aggregation of the NEE: interpretation of the results obtained at the national and European scales

In order to examine here the dependency of the NEE uncertainty reduction to increasing spatial scales of aggregation for the analyses in July and December, we chose five locations at which we define centered areas with increasing size for which uncertainties in the average NEE are derived. These stations are located using the green circles in Fig. 1c. The five locations correspond to three observing sites of ICOS23: Trainou (TRN), Ochsenkopf (OXK), Plateau Rosa (PRS); one site of ICOS50: SMEAR II-ICOS Hyytiälä (HYY); and one point in Sweden which does not correspond to any site of the ICOS networks tested here, called SW1 hereafter (Fig. 1c). We compute the uncertainty reductions of the two-week mean NEE for July and December over 5 square (in degrees) domains centered around each site of  $1.5^\circ \times 1.5^\circ$ ,  $2.5^\circ \times 2.5^\circ$ ,  $3.5^\circ \times 3.5^\circ$ ,  $4.5^\circ \times 4.5^\circ$  and  $10.5^\circ \times 10.5^\circ$  size (which corresponds to surfaces of different size in terms of  $\text{km}^2$ ). Depending on their location and on their size, the corresponding domains expand over areas of Europe that are more or less constrained by the inversion at the pixel scale. But the variations of the uncertainty reduction when increasing the size of these domains are also strongly driven by the spatial correlations in the prior and posterior uncertainty. The results are displayed in Fig. 5.

Interactive Discussion

The five locations used for this analysis are representative of the diversity of the situation regarding the differences between grid scale uncertainty reduction in July and in December. While the uncertainty reduction is slightly larger in July than in December for TRN, much larger in July for PRS and HYY, it is slightly larger in December at OXK and much larger in December at SW1. Furthermore, the values for these grid scale uncertainty reductions range from 15 to 50 % in July and from 7 to 47 % in December at these locations (Fig. 5).

The maximum scores of uncertainty reduction occur for spatial scales of aggregation ranging from  $10^5$  to  $10^6$  km<sup>2</sup> when considering the sites located in Western Europe. These scales approximately correspond to the range of the sizes of the European countries and it is larger than the typical area of correlation of the prior uncertainty (as defined by prior correlation lengths of 250 km). Increasing the spatial resolution generally increases the uncertainty reduction since posterior uncertainties have generally smaller correlation lengths than prior uncertainties, due to the spatial attribution error when trying to link the measurement information to local fluxes despite the atmospheric mixing. This explains the increase of uncertainty reduction from the grid scale to the “national scales”. This also explains why, for a given regional density of the measurement network, larger countries bear larger uncertainty reductions (Fig. 4). However, above such national scales, the corresponding domains include parts of Eastern Europe being poorly sampled by the ICOS23 network which explains the decrease in uncertainty reduction.

The convergence of the results around TRN, PRS and OXK to nearly 65 % uncertainty reduction in both December and July for the western European domain, and of the results at all sites to 53 % in July and 66 % in December for the whole Europe, when increasing the spatial averaging area, starts between the same  $10^5$  and  $10^6$  km<sup>2</sup> (national scale) averaging areas. For smaller areas, the differences between July and December or between different spatial locations stay similar to what is seen at the  $0.5^\circ \times 0.5^\circ$  scale.

Interactive Discussion

all spatial scales. This is because it decreases the prior uncertainty at every scale while decreasing the ability of the inversion system to extrapolate in space the information from measurement sites based on the knowledge about spatial correlations of the prior uncertainties. At 0.5° resolution, the areas of high uncertainty reduction narrows around the measurement sites and the smaller overlap of the areas of influence of these sites limits the highest local values of uncertainty reduction to 40–50 % while typical values in Western Europe now range from 20 to 40 % instead of 30 to 65 % when using  $\mathbf{B}_{250}$  (see Sect. 2.2.2 for the definition of the  $\mathbf{B}$  matrices). The uncertainty reduction for countries such as the UK, Germany and Spain decreases when the e-folding correlation length is lowered from 250 to 150 km, from more than 75–80 % to less than 70 %. For the full European domain, it decreases from 64 to 47 %.

Even though these decreases can be very large, it is critical to keep in mind that they refer to uncertainty reductions compared to a prior uncertainty which is decreased by the new configuration of  $\mathbf{B}$  (as illustrated at the country scale in Fig. A1). The posterior uncertainty in the European and two-week mean NEE in July using ICOS66 is decreased from  $\sim 33$  to  $29 \text{ TgC month}^{-1}$  when changing the configuration of  $\mathbf{B}$  from  $\mathbf{B}_{250}$  to  $\mathbf{B}_{150}$  (Table 1). Similarly, the posterior uncertainty is generally smaller at the national scale when changing the configuration of  $\mathbf{B}$  from  $\mathbf{B}_{250}$  to  $\mathbf{B}_{150}$  (Fig. A2). We thus have an expected situation for which improving the knowledge on the prior NEE improves that of the posterior NEE even if in our case, the improvement of the knowledge on the prior NEE which is tested here also decreases the ability to extrapolate in space the information from the atmospheric measurements. However, of note is that when changing the configuration of  $\mathbf{B}$  from  $\mathbf{B}_{250}$  to  $\mathbf{B}_{150}$ , we do not improve the knowledge on the prior NEE at the model grid 0.5° resolution (since modifying the correlations but not the SDs in  $\mathbf{B}$ ). Given the lower uncertainty reduction when using  $\mathbf{B}_{150}$ , the posterior uncertainties are higher at 0.5° resolution when changing the configuration of  $\mathbf{B}$  from  $\mathbf{B}_{250}$  to  $\mathbf{B}_{150}$  (Fig. A3).

### 3.4 Sensitivity to the observation error

The impact of dividing the SD of the observation error by two in the inversion configuration is tested using ICOS50 in July (compare Figs. 7a and 10b, Figs. 8a and 11b and the corresponding curves in Fig. 9). The decrease of observation error increases the weight of the measurements in the inversion and the resulting uncertainty reduction. This increase is visible at all spatial scales for the aggregation of the NEE, and relatively constant as a function of these spatial scales except at the European scale for which it is quite smaller, from 64 to 67 %. This provides the highest scores of uncertainty reduction of this study at any spatial scales, the impact of division of the observation error by two being larger than that of increasing the ICOS network configuration from ICOS50 to ICOS66.

## 4 Synthesis and conclusions

We assessed the potential of CO<sub>2</sub> mole fraction measurements from three configurations of the ICOS atmospheric network to reduce uncertainties in two-week mean European NEE at various spatial scales in summer and in winter. This assessment is based on a regional variational inverse modeling system with parameters consistent with the knowledge on uncertainties in prior estimates of NEE from ecosystem models and in atmospheric transport models. The results obtained with the various experiments from this study indicate an uncertainty reduction which ranges between ~ 50 and 80 % for the full European domain, between ~ 70 and 90 % for large countries in Western Europe (such as France, Germany, Spain, UK), where the ICOS network are denser, but below 50 % in much cases for eastern countries where there are few ICOS sites even with the ICOS66 configuration. At 0.5° resolution, if excluding results when using **B**<sub>150</sub> (for which the uncertainty reduction is applied to a different prior uncertainty), uncertainty reductions range from 30 to 65 % in the dense parts of the networks (between northern Spain and eastern Germany) while it is generally below 30 % east of Germany

## On the potential of ICOS atmospheric CO<sub>2</sub> measurement network

N. Kadygrov et al.

**Figure 1.** Site location for the different ICOS network configurations used in this study: **(a)** ICOS23 **(b)** ICOS50 **(c)** ICOS66. Dark blue circles correspond to ICOS23 and the red circles are the new sites for ICOS50 and ICOS66 compared to ICOS23. The European domain ( $\sim 6.8 \times 10^6 \text{ km}^2$  of land surface) covered by these figures corresponds to the domain of the configuration of the CHIMERE atmospheric transport model used in this study. The red rectangle in **(c)** corresponds to a western European domain (WE domain,  $\sim 3.5 \times 10^6 \text{ km}^2$  of land surface) which is used for some of the present analysis because it is significantly better sampled by the ICOS networks than other areas. Green circles in **(c)** are the station locations used for the study of the uncertainty reduction as a function of the spatial scale of the aggregation around each station (in Sect. 3.1.4).

## On the potential of ICOS23 atmospheric CO<sub>2</sub> measurement network

N. Kadygrov et al.

**Figure 2.** Uncertainty reduction (theoretically comprised between 0 and 1) for two-week mean NEE at 0.5° resolution in July (a) and in December (b) when using ICOS23 (red dots) and the reference inversion setup. Red/blue colors indicate relatively high/low uncertainty reduction (with min = 0, max = 0.68 in the color scale).

**Figure 3.** SDs ( $\text{g C m}^{-2} \text{ day}^{-1}$ ) of the prior (**a, b**) and posterior (**c, d**) uncertainties in two-week mean NEE at  $0.5^\circ$  resolution for (**a, c**) July and (**b, d**) December. Posterior uncertainties are given for inversions using ICOS23 (red dots) and the reference inversion setup. Red/blue colors indicate relatively high/low uncertainties (with  $\text{min} = 0 \text{ g C m}^{-2} \text{ day}^{-1}$ ,  $\text{max} = 3 \text{ g C m}^{-2} \text{ day}^{-1}$  in the color scale).

## On the potential of ICOS23 atmospheric CO<sub>2</sub> measurement network

N. Kadygrov et al.

**Figure 4.** Uncertainty reduction (theoretically comprised between 0 and 1) for two-week mean NEE at the country scale for July **(a)** and December **(b)** when using ICOS23 and the reference inversion configuration. Red/blue colors indicate relatively high/low uncertainty reduction (with min = 0, max = 0.95 in the color scale).

**On the potential of ICOS atmospheric CO<sub>2</sub> measurement network**

N. Kadygrov et al.

**Figure 5.** Uncertainty reduction (theoretically comprised between 0 and 1) for two-week mean NEE in July and December 2007 using ICOS23 and the reference configuration of the inversion, as a function of the size (logarithmic scale) of the spatial averaging area around each station TRN (red curves), PRS (blue curves), HYY (green curves), OXK (pink curves) and SW1 (grey curves; see the locations in Fig. 1c). Solid and dash lines correspond to results for July and December respectively (see the legend within the figure). The results of uncertainty reduction for the whole European domain are included (red rectangle). The results for the western European domain defined in Fig. 1c are included on curves corresponding to sites which are located in this domain (TRN, PRS and OXK, see the green rectangle).

## On the potential of ICOS atmospheric CO<sub>2</sub> measurement network

N. Kadygrov et al.

**Figure 6.** Correlations of the posterior uncertainties in two-week mean NEE between Germany and the other European countries in July (a) and December (b) from the reference inversions with ICOS23. Germany is masked in white. Red/blue colors indicate relatively high positive/negative correlations (with min = -0.45, max = 0.45 in the color scale).

**Figure 7.** Uncertainty reduction (theoretically comprised between 0 and 1) for two-week mean NEE at 0.5° resolution in July (**a, b**) and December (**c, d**) when using ICOS50 (**a, c**) and ICOS66 (**b, d**) and the reference inversion configuration. Red dots corresponds to the ICOS23 (**a, c**) or ICOS50 (**b, d**) sites while white dots correspond to the additional sites included in ICOS50 or ICOS66 respectively. Red/blue colors indicate relatively high/low uncertainty reduction (with min = 0, max = 0.68 in the color scale).

## On the potential of ICOS atmospheric CO<sub>2</sub> measurement network

## On the potential of ICOS atmospheric CO<sub>2</sub> measurement network

N. Kadygrov et al.

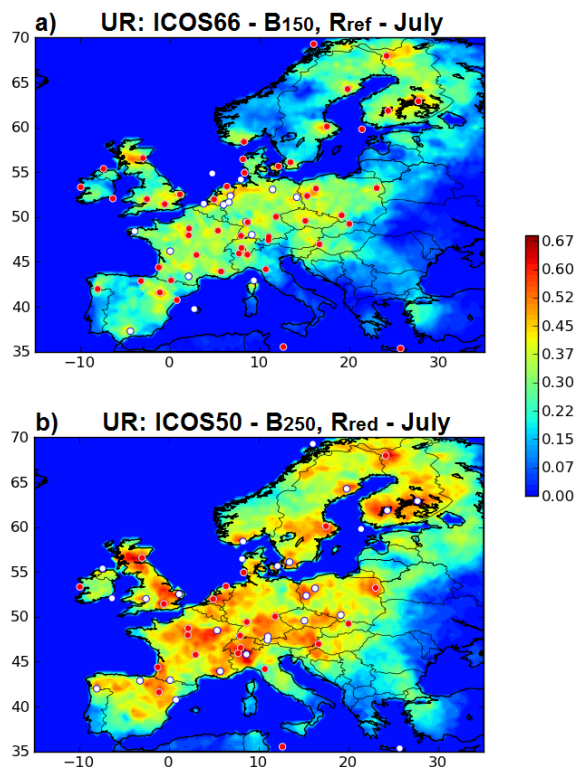

**Figure 9.** Uncertainty reduction (theoretically comprised between 0 and 1) for two-week mean NEE for July 2007 as a function of the size (in logarithmic scale) of the spatial averaging area centered on **(a)** SW1, **(b)** HYY, **(c)** TRN, **(d)** OXK, and **(e)** PRS. Red, orange, green lines: results with the reference configuration of the inversion using ICOS23, ICOS50 and ICOS66 respectively; blue: results when using ICOS50 and the inversion configuration with  $\mathbf{R} = \mathbf{R}_{\text{red}}$ ; pink: results when using ICOS66 and the inversion configuration with  $\mathbf{B} = \mathbf{B}_{150}$ . The results of uncertainty reduction for the whole European domain are included systematically. The results for the western European domain defined in Fig. 1c are included on curves corresponding to sites which are located in this domain (TRN, PRS and OXK).
