The microwave spectrum of the NH₃-N₂ van der Waals complex has been observed in a supersonic molecular jet expansion via broadband (2-8 GHz) chirped-pulse Fourier-transform microwave spectroscopy. Two pure rotational R(0) transitions (J = 1 - 0) with different hyperfine structure patterns were detected. One transition belongs to the (ortho)-NH₃-(ortho)-N₂ nuclear spin isomer in the ground K = 0 state reported earlier [G. T. Fraser et al., J. Chem. Phys. 84, 2472 (1986)], while another one is assigned to the (para)-NH₃-(para)-N₂ spin isomer in the K=0 state not reported before (K is theprojection of the total angular momentum J on the intermolecular axis). The complicated hyperfine structure arising from three quadrupole ¹⁴N nuclei of NH₃-N₂ was resolved for both transitions, and the quadrupole coupling constants associated with the NH₃ and N₂ subunits were precisely determined for the first time. These constants provided the dynamical information about the angular orientation of ammonia and nitrogen indicating that the average angle between the C_3 axis of NH₃ and the N₂ axis is about 66°. The average van der Waals bond lengths are slightly different for (ortho)-NH₃-(ortho)-N₂ and (para)-NH₃-(para)-N₂ and amount to 3.678 Å and 3.732 Å, respectively. Similar results for the deuterated isotopologues, ND₃-N₂, NHD₂-N₂, and NH₂D-N₂, and their nuclear spin isomers were also obtained thus confirming and extending the analysis for the parent NH₃–N₂ complex. Published by AIP Publishing. https://doi.org/10.1063/1.5063346

I. INTRODUCTION

A nuclear hyperfine structure in molecular rotational spectra arises from magnetic and electric interactions of the molecular fields with the nuclear moments. Observation of the resulting splittings of the energy levels into components provides detailed information on the molecular electronic structure and chemical bonds. 1,2 In the case of weakly bound molecular complexes, the hyperfine structure parameters (quadrupole coupling, spin-spin coupling, and spin-rotation constants) might provide additional valuable information about intermolecular dynamics and the interaction potential.³ Moreover, the hyperfine structure of rotational spectra is so specific that its analysis may help to distinguish the spectra originating from different nuclear spin isomers for those complexes that contain symmetric parent monomer(s). However, the relatively low binding energy of weakly bound complexes can give rise to large amplitude internal motions which complicate the experimental determination of hyperfine parameters, both for problems in resolving hyperfine structure components and the complexity of the hyperfine spectral pattern itself.

Spectroscopically, NH_3-N_2 is an interesting case of a weakly bound system that exhibits four nuclear spin isomers, which are formed when ortholpara (olp) NH_3 combines with (olp) N_2 . Because of the nuclear spin effects, the first excited internal rotor states of both monomers are metastable and are anticipated to be populated in the cold supersonic expansion of the molecules used for the formation of complexes. Rotational transitions originating from these states are therefore also expected in the spectra, besides the ground state transitions, thus probing the angular anisotropy of the intermolecular potential much more extensively.

The spectra of the NH_3-N_2 complex were first studied in the microwave (MW) region by Fraser *et al.* in 1986.⁴

⁶Ikerbasque, Basque Foundation for Science, E-48013 Bilbao, Spain

The present study demonstrates the successful application of chirped-pulse Fourier-transform microwave (CP-FTMW) spectroscopy in the study of the NH₃–N₂ van der Waals complex revealing the complicated hyperfine structure arising from three quadrupole ¹⁴N nuclei. NH₃–N₂ is of particular interest because molecular nitrogen is the main component of many atmospheres of our solar system and extrasolar planetary systems, and ammonia is the most abundant alkaline gas of these media. High-level spectroscopic information about the structure and intermolecular dynamics of NH₃–N₂ is required in various areas of atmospheric sciences, e.g., atmospheric physics and chemistry.

a)Electronic mail: surin@isan.troitsk.ru

They found two series of transitions in the 6-27 GHz range using the molecular beam electric resonance (MBER) technique. The main series of four transitions was assigned as having K = 0 (the approximate quantum number K is the projection of total angular momentum J on the intermolecular axis), and a second pair of lines was assigned as having K = 1. These first observations were followed by more detailed millimeter-wave (mmW) studies.^{5,6} As a result, a number of series of pure rotational transitions were assigned in terms of K = 0 and K = 1 states of NH₃–N₂ involving the possible nuclear spin isomers of the complex.⁵ Not all of these assignments were certain however, since the observed mmW series contained transitions only with high J-numbers (larger than 10).

The hyperfine structure arising from the three 14 N nuclei was only partially resolved in the first MW study of NH₃– N_2^4 and could not be analyzed. The current paper presents such analysis for the R(0) transition of the (o)-NH₃–(o)-N₂ spin isomer in the ground K=0 state reported earlier⁴ and for another R(0) transition assigned to the (p)-NH₃–(p)-N₂ spin isomer in the K=0 state not reported before. The deuterated ammonia species, ND₃–N₂, NHD₂–N₂, and NH₂D–N₂, showing similar hyperfine structure, were also detected, thus confirming the new assignments for the parent species. The resulting quadrupole coupling constants associated with NH₃ (ND₃, NHD₂, and NH₂D) and N₂ were precisely determined for the first time providing the dynamical information about the angular orientation of the ammonia and nitrogen subunits in the complex.

Another important result of the present study is the nonobservation of the K = 0 state for (p)-NH₃–(p)-N₂ (not the one mentioned above), which was expected based on the earlier analysis⁵ and one more K = 0 state for (o)-NH₃–(p)-N₂. This fact suggests revision of the assignments in the K numbers for the reported mmW transition series.⁵

II. EXPERIMENTAL DETAILS

The rotational spectra of NH₃-N₂ were detected using a broadband (2-8 GHz) chirped-pulse Fourier-transform microwave (CP-FTMW) spectrometer, the details of which are available elsewhere. The microwave excitation pulses (4 μ s) are directly generated on an arbitrary waveform generator (AWG), amplified to 300 W, and broadcast into a vacuum chamber where they interact with the cold ensemble of molecules. In order to reduce measurement time and sample consumption, the "fast-frame" scheme was employed. Each sample injection was followed by a pulse train of eight excitation pulses spanning from 2 to 8 GHz. The molecular emission or free induction decay (FID) was then collected in the time domain for 40 μ s after each excitation pulse. The Fourier transform of the averaged time trace yielded the frequency domain spectrum after the application of a Kaiser-Bessel window to improve the baseline resolution.

The sample of a gas mixture of 0.5%-1% of NH_3 and few percent of N_2 in Ne was injected through a pulsed pinhole nozzle into an evacuated chamber at a backing pressure in the range of 6-9 bars. The nozzle (General Valve, Series 9) with an orifice of 1 mm diameter was operated at a repetition rate of

9 Hz. The fast-frame scheme yielded an effective repetition rate of 72 Hz. The spectra of the ND₃, ND₂H, and NDH₂ containing complexes were recorded using an isotopically enriched sample of ND₃ (99% D). Partly deuterated species were produced by H/D exchange with remaining H₂O inside the sample system. In all the cases, the final spectra comprised 1.2×10^6 FIDs.

The full width at half-height for each line was about 60 kHz, and the uncertainty in the line center frequencies was estimated to be $\approx 5 \text{ kHz}$. At a sufficiently high resolution of the CP-FTMW spectrometer, the hyperfine structure due to three ^{14}N nuclei of the N_2 and NH_3 (ND_3 , ND_2H , and NDH_2) parts of the complexes was clearly resolved.

III. OBSERVED ROTATIONAL TRANSITIONS AND ANALYSIS

A free internal rotation model provides a useful starting point to consider the energy levels of NH₃-N₂, and the nuclear spin modifications of the parent molecules remain important in the complex. Due to the nuclear spin statistics of N_2 , (o)– N_2 complexes with total nuclear spin $I_{N_2} = 0$ and 2 have their lowest internal rotor state with $j_{N_2} = 0$, while (p)-N₂ complexes with $I_{N_2} = 1$ have their lowest internal rotor state with $j_{N_2} = 1$, where j_{N_2} denotes the rotational angular momentum of N₂. Due to the three equivalent protons, the NH₃ part has also two nuclear spin states, (o)-NH₃ ($I_{NH_3} = 3/2$) and (p)-NH₃ $(I_{\rm NH_3} = 1/2)$ with the corresponding lowest rotational levels $(j_k)_{NH_3} = 0_0$ and $(j_k)_{NH_3} = 1_1$, where j and k denote the angular momentum of NH3 and its projection on the symmetry axis. In total, four different nuclear spin species occur for the NH_3-N_2 complex: (o)- $NH_3-(o)-N_2$, (p)- $NH_3-(o)-N_2$, (o)- $NH_3-(p)-N_2$, and $(p)-NH_3-(p)-N_2$. These spin isomers behave as different molecules because they do not interconvert at the time scale of the experiment, due to quantum-mechanical symmetry rules.

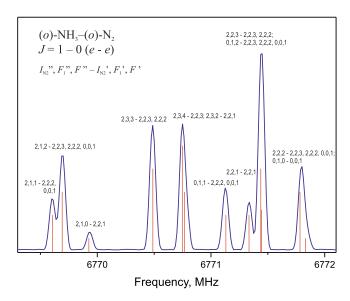

FIG. 1. Nuclear hyperfine structure of the R(0) pure rotational transition of (o)-NH₃–(o)-N₂. The stick spectrum is simulated from the nuclear quadrupole coupling constants obtained from a fit of the respective transitions.

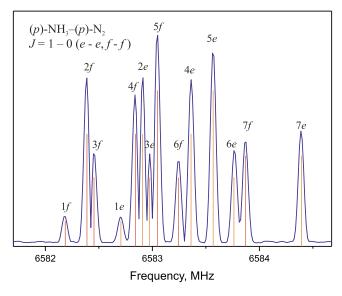

FIG. 2. Nuclear hyperfine structure of the R(0) pure rotational transition of (p)-NH₃–(p)-N₂. The hyperfine pattern consists of two similar groups of seven peaks, designated by spectroscopic parity e and f correspondingly. The stick spectrum is simulated from obtained nuclear quadrupole coupling constants.

A strong feature at 6.77 GHz was observed as expected for the R(0) transition of the (o)-NH₃-(o)-N₂ spin isomer in the ground K = 0 state.⁴ In contrast to the previous MW study,⁴ the hyperfine structure was now clearly resolved representing nine peaks spread over a 2.5 MHz region, as shown in Fig. 1. Another strong feature consisting of 14 peaks distributed also within 2.5 MHz was found at lower frequencies around 6.58 GHz, as shown in Fig. 2. In fact, looking closely, one can see that these 14 peaks consist of doublets, that is, they represent two similar series of seven lines, shifted relative to each other by approximately 0.5 MHz. For clarity, the paired components in Fig. 2 are numbered as 1e and 1f, 2e and 2f, etc. For the isoelectronic NH₃-CO complex, ^{9,10} similar doubling of rotational transitions was associated with (p)-NH₃ and its absence with (o)-NH₃, and it was also assumed⁵ that NH₃-N₂ behaves in a similar fashion. Our hyperfine structure analysis confirmed this fact and showed that the observed pattern at 6.58 GHz corresponds to the R(0) transition of the $(p)-NH_3-(p)-N_2$ nuclear spin isomer. Here in Fig. 2, we use the spectroscopic parity labels $e(\epsilon = +1)$ and $f(\epsilon = -1)$ to assign the parity p of individual levels according to the

relation $p = \varepsilon(-1)^J$, and the *elf* ordering was assumed to be the same as for (p)-NH₃–CO.¹⁰ In case of (o)-NH₃–(o)-N₂, only *e*-symmetry refers to all K = 0 levels, therefore we omitted parity labels in Fig. 1. The R(0) transition of (p)-NH₃–(p)-N₂ was not observed in the earlier MW study⁴ and was also not expected from available mmW data.^{5,6} Indeed, from the mmW series of the four R(11)-R(14) transitions assigned to the K = 0 state of (p)-NH₃–(p)-N₂,⁵ the R(0) line of this spin isomer was predicted at 6.69 GHz, but no feature was detected at this frequency.

An additional criterion for assigning the observed nuclear spin isomers of NH₃–N₂ is relative intensities of their transitions. On the basis of nuclear spin statistics, we expect an intensity ratio of 2:1 for complexes composed of (o)- and (p)-N₂, respectively. For NH₃, the spin statistics are also 2:1 for *ortho/para*, but in spite of the higher multiplicity of the *ortho* nuclear spin states, the larger number of the *para* rotational levels results in approximately equal populations of the (o)- and (p)-NH₃ species. The observed intensity ratio of (o)-NH₃–(o)-N₂ to (p)-NH₃–(p)-N₂ for J=1-0 transitions is 2.4. This value agrees reasonable with the above consideration taking into account the variations of the spectrometer response over the frequency range.

The resolved individual hyperfine components of the (o)-NH₃–(o)-N₂ and (p)-NH₃–(p)-N₂ R(0) transitions are given in Tables I and II, respectively. The assigned quantum numbers correspond to the coupling scheme: $\mathbf{I}_{\mathrm{N}_2} = \mathbf{I}_1 + \mathbf{I}_2$, $\mathbf{F}_1 = \mathbf{I}_{\mathrm{N}_2} + \mathbf{J}$, and $\mathbf{F} = \mathbf{F}_1 + \mathbf{I}_{\mathrm{N}}$, where \mathbf{I}_1 and \mathbf{I}_2 are the nuclear spins of two identical ¹⁴N nuclei $(I_1 = I_2 = 1)$, $\mathbf{I}_{\mathrm{N}_2}$ is their sum $(I_{\mathrm{N}_2} = 0, 1, 2)$, and \mathbf{I}_{N} is the nuclear spin of the ¹⁴N nucleus $(I_{\mathrm{N}} = 1)$ in the ammonia molecule.

^aFixed to the value scaled from (o)-NH₃-(o)-N₂.

The change of NH₃ for ND₃ in the gas mixture allowed the observation of similar R(0) transitions for (o)-ND₃–(o)-N₂ and (p)-ND₃–(p)-N₂ as well as partly deuterated NHD₂–(o)-N₂ and NDH₂–(o)-N₂ species. They could be easily assigned due to the expected line positions and hyperfine patterns analogous to those of the parent isotopologue. The partial substitution in the case of NHD₂ and NDH₂ reduces the symmetry of the ammonia monomers and, although two nuclear spin isomers remain, there is no metastable excited internal rotor state (similar to (p)-NH₃ and (p)-ND₃) associated with them. The corresponding levels cannot be populated at the low rotational temperature of the jet (1-3 K) and only transitions correlating with the (o)-NH₃–(o)-N₂ spin isomer were detected for NHD₂–(o)-N₂ and NDH₂–(o)-N₂.

Inversion tunneling splitting was expected in the ground internal rotor state for the (o)-ND₃-, NHD₂-, and NDH₂-containing complexes with relative spin statistical weights for symmetric and asymmetric components of 10:1, 6:3, and 1:3, respectively, in contrast to the spectrum of the (o)-NH₃-(o)-N₂ isotopologue in which the symmetric inversion component has a nuclear spin weight of zero. Probably this separation of inversion components was too small to observe, and it was also not detected for the related (o)-ND₃-CO, NHD₂-CO, and NDH₂-CO complexes.⁴ Also no additional D $(I_D$ = 1) hyperfine splittings for all deuterated isotopologues could be resolved, which can be expected to be below the FWHM linewidths of about 60 kHz.¹¹

^aThe mean center frequencies were used in the fitting procedure.

The assigned individual hyperfine components of the R(0) transitions for (o)-ND₃–(o)-N₂, NHD₂–(o)-N₂, and NDH₂–(o)-N₂ are listed in Table I. The assigned hyperfine components for the J=1-0 transition of (p)-ND₃–(p)-N₂ are given in Table II.

The transitions of NH₃-N₂ and deuterated isotopologues assigned in this work were fitted using the PGOPHER program, which is open to the public. 12 All complexes in the K = 0 state were treated as a linear molecule, and two ^{14}N nuclei of the nitrogen molecule were considered as identical in hyperfine structure analysis according to the coupling scheme mentioned above: $I_{N_2} = I_1 + I_2$, $F_1 = I_{N_2} + J$, and $\mathbf{F} = \mathbf{F}_1 + \mathbf{I}_N$. In the case of the (o)-NH₃-(o)-N₂ spin isomer, the previously observed mmW transitions^{5,6} were also included in the fitting procedure with a weight of 0.1 relative to our measurements in accordance with their experimental accuracy. The MW data from Fraser et al.4 were not used in the fits because of their unclear/unresolved hyperfine/splitting structure. Since we have only one transition for (p)-NH₃-(p)-N₂ and each deuterated complex, their centrifugal distortion parameters D were fixed to quantities that were obtained by scaling corresponding values for the main isotopologue using relations for reduced masses. For the (p)-NH₃–(p)-N₂ and (p)- $ND_3-(p)-N_2$ transitions exhibiting doubling, the mean center frequencies were used in the fit analysis. The results of the fits are given in Tables III and IV. The weighted value of the root mean squared deviation is $\sigma_{\text{fit}} = 78 \text{ kHz for } (o)\text{-NH}_3\text{-}(o)\text{-N}_2.$

IV. DISCUSSION AND CONCLUSIONS

The determined rotational constant B and centrifugal distortion parameter D for (o)-NH₃–(o)-N₂ (Table III) agree well with the previous mmW results, $B = 3385.634\,91(910)$ MHz and D = 111.3343(368) kHz.⁶ These values can be also compared with those of the closely related (o)-NH₃–CO complex in the ground K = 0 state: $B = 3485.762\,76(63)$ MHz and D = 110.4157(450) kHz.¹⁰ Overall, the B values of NH₃–(o)-N₂ are lower than those of (o)-NH₃–CO by about 100 MHz, indicating a slightly longer effective intermolecular distance. The obtained rotational constant B for the new K = 0 state of (p)-NH₃–(p)-N₂ (Table IV) is 94 MHz less than the corresponding value for (o)-NH₃–(o)-N₂. In the case of NH₃–CO, such difference is only 8 MHz¹⁰ considering that

^bFixed to the value from (o)-NH₃-(o)-N₂.

the (p)-NH₃–CO $(j_{N_2}, j_{CO}) = (1, 1)$ state is analogous to the (p)-NH₃–(p)-N₂ $(j_{NH_3}, j_{N_2}) = (1, 1)$ state.

Dynamical information about the orientation of the ammonia and nitrogen units within the van der Waals complex can be obtained from the determined quadrupole coupling constants using the expression, $eqQ = (eqQ)_0 \langle P_2(\cos\theta_{\text{NH3/N2}}) \rangle$, where $(eqQ)_0$ is the quadrupole coupling constant for the free NH₃ (ND₃) molecule, -4.0898 MHz¹³ (-4.0831 MHz¹⁴), or the N₂ molecule, -5.372 MHz, ¹⁵ and θ_{NH_3/N_2} is the angle between the intermolecular axis and the C_3 axis of NH₃ (ND₃) or the N₂ axis, respectively. This expression assumes that complexation has little effect on the electron distribution around the ¹⁴N nuclei and that the angular brackets represent averaging over the internal motions of NH₃ (ND₃) or N₂ in the complex. We assume also that the weighted average of the free NH₃ and ND_3 $(eqQ)_0$ values is a suitable approximation for the $(eqQ)_0$ values of NDH₂ and ND₂H. Solving this expression for θ_{NH_3} and θ_{N_2} yields two possible angles $43.8^{\circ}/136.2^{\circ}$ for NH₃ and $69.8^{\circ}/110.2^{\circ}$ for N₂ in (*o*)-NH₃–(*o*)-N₂. From the *ab initio*¹⁰ and experimental⁴ studies of the related NH₃-CO complex, it was found that in the ground state it has a T-shaped structure with the N atom closest to the CO subunit. Assuming a similar geometry for NH₃-N₂, the first two values $\theta_{NH3} = 43.8^{\circ}$ and $\theta_{\rm N2}$ = 69.8° were chosen as shown in Fig. 3, resulting in the angle between the C_3 axis of NH₃ and the N₂ axis of 66.4°.

The Legendre polynomial factor $\langle P_2(\cos\theta_{\rm NH_3/N_2})\rangle$ in the above equation will be zero if the ammonia or nitrogen subunit undergoes free internal motion. For (o)-NH₃-(o)-NP₃,

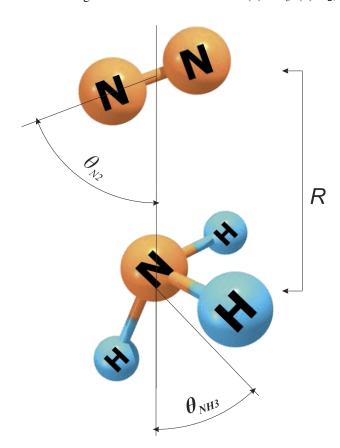

FIG. 3. The angular orientation of the NH₃ ($\theta_{\text{NH}_3} = 43.8^{\circ}$) and N₂ ($\theta_{\text{N}_2} = 69.8^{\circ}$) monomers in the (o)-NH₃-(o)-N₂ complex as determined from the nuclear quadrupole structure analysis. The average van der Waals bond length R was estimated to be 3.678 Å.

 $\langle P_2(\cos\theta_{\rm NH_3})\rangle$ is 0.2823, a value that is remarkably large in magnitude compared to -0.066 for the (o)-NH₃-Ne¹⁶ and -0.086 for the (o)-NH₃-Ar¹⁷ complexes. The $\langle P_2(\cos\theta_{N_2})\rangle$ value for (o)-NH₃-(o)-N₂ is -0.3208, that is, only slightly larger in magnitude than -0.2189 for the N_2 -Ne¹⁵ and -0.2997for N₂-Ar¹⁸ complexes. This suggests a significantly hindered internal motion of the NH3 moiety and a similar degree of hindered motion of the N₂ monomers in (o)-NH₃-(o)-N₂ as compared to their complexes with rare gas atoms. The same sign of the $\langle P_2(\cos \theta_{\rm N_2}) \rangle$ values assumes an "on average" more perpendicular orientation of N2 to the intermolecular axis in (o)-NH₃-(o)-N₂ similar to N₂-Ne and N₂-Ar. The different sign of $\langle P_2(\cos\theta_{\rm NH_3})\rangle$ as compared to complexes of NH₃ with rare gas atoms assumes an "on average" more parallel orientation of NH₃ to the intermolecular axis, in contrast to a more perpendicular arrangement in case of Ar– and Ne–(o)-NH₃. Indeed, the $\langle P_2(\cos\theta_{\rm NH_3})\rangle$ value is very close to the value of (o)-NH₃-(o)-H₂ (0.306), ¹⁹ for which the equilibrium structure was found to be axial, with the C_3 symmetry axis of ammonia collinear with the intermolecular axis.²⁰ The magnitude of $\langle P_2(\cos\theta_{\rm NH_3})\rangle$ slightly increases with increasing deuterium substitution. For (o)-N2 paired with NH3, NDH2, ND2H, and ND_3 , the corresponding values are 0.2824, 0.2868, 0.2915, and 0.2941. This can be attributed to the larger tunneling mass and lower zero-point energies of the heavier complexes, resulting in stronger localization of the ammonia unit.

As can be seen from Tables III and IV, the determined quadrupole coupling constants and the Legendre polynomial factors for (p)-NH₃–(p)-N₂ are very similar to those of (o)-NH₃–(o)-N₂. This fact suggests a similar angular orientation of the two spin isomers with a slightly different intermolecular distance. From the derived molecular constants, the average van der Waals bond lengths $\langle R \rangle$ were calculated to be 3.678 Å and 3.732 Å for (o)-NH₃–(o)-N₂ and (p)-NH₃–(p)-N₂, respectively, using the formula, 21

$$\begin{split} I_b &= M \left\langle R^2 \right\rangle + \frac{I_\perp^{\text{NH}_3}}{2} \left(1 + \left\langle \cos^2 \vartheta_{\text{NH}_3} \right\rangle \right) + \frac{I_{||}^{\text{NH}_3}}{2} \left\langle \sin^2 \vartheta_{\text{NH}_3} \right\rangle \\ &+ \frac{I_{\text{N}_2}}{2} \left(1 + \left\langle \cos^2 \vartheta_{\text{N}_2} \right\rangle \right), \end{split}$$

where $I_{\rm b}$ is the moment of inertia of the complex obtained from the experimental rotational constant, $M = \frac{m_{\rm NH_3}m_{\rm N_2}}{(m_{\rm NH_3}+m_{\rm N_2})}$ is the pseudodiatomic reduced mass, and $I_{\parallel}^{\rm NH_3}$, $I_{\perp}^{\rm NH_3}$, and $I_{\rm N_2}$ are the effective moments of inertia of the free ammonia (perpendicular and parallel to C_3 axis)²² and molecular nitrogen.²³

From a previous mmW study of NH₃–N₂,⁵ we could expect the observation of one more K=0 state for (p)-NH₃–(p)-N₂ as well as the K=0 state for (o)-NH₃–(p)-N₂ spin isomers. Both these states were not detected in spite of significant resource in sensitivity as can be seen from the signal to noise ratio for the measured NH₃–N₂ transitions. No corresponding features were found also in the spectra of complexes containing the ND₃–N₂ isotopologues. Analyzing the results obtained earlier for the NH₃–CO complex¹⁰ and considering that the (p)-NH₃–CO $(j_{\rm NH_3},j_{\rm CO})=(1,1)$ state is analogous to the (p)-NH₃–(p)-N₂ $(j_{\rm NH_3},j_{\rm N_2})=(1,1)$ state, we can suppose that the observed series⁵ for the latter belongs to the K=2 state, located quite closely $(1.12 \text{ cm}^{-1} \text{ in case of } (p)$ -NH₃–CO) to

the K=0 state. For the (o)-NH₃-CO $(j_{\rm NH_3},j_{\rm CO})=(0,1)$ state, correlating to the (o)-NH₃-(p)-N₂ $(j_{\rm NH_3},j_{\rm CO})=(0,1)$ state, no K=0 levels were detected at all and according to the *ab initio* calculations, ¹⁰ such levels would be located at 24.13 cm⁻¹ above the lowest K=1 state of this spin isomer. This results in very low population of the expected K=0 levels and makes some doubt in the correct assignment of the corresponding mmW transition series ⁵ to the (o)-NH₃-(p)-N₂ spin isomer.

In summary, from high-resolution rotational spectroscopy of the weakly bound NH₃-N₂ complexes and their deuterated isotopologues, hyperfine interactions of ammonia and nitrogen and their angular orientation and internal rotational dynamics within the complexes have been revealed. The earlier mmW study of NH₃-N₂⁵ reported a number of series of pure rotational transitions tentatively assigned in terms of K = 0 and K = 1 states of the possible nuclear spin isomers of the complex. Two expected K = 0 states for $(p)-NH_3-(p)-N_2$ and $(o)-N_3$ $NH_3-(p)-N_2$ were not detected in our experiment, thus calling the proposed assignments in K of these series into question. Future observations of low-J transitions, e.g., the R(1) and R(2) transitions, as well as theoretical studies of the potential energy surface and bound state calculations will definitively establish the K values for all observed series of four different NH_3-N_2 spin isomers.
