ABSTRACT

We consider black hole formation in failed supernovae when a dense circumstellar medium (CSM) is present around the massive star progenitor. By utilizing radiation hydrodynamical simulations, we calculate the mass ejection of blue supergiants and Wolf-Rayet stars in the collapsing phase and the radiative shock occurring between the ejecta and the ambient CSM. We find that the resultant emission is redder and dimmer than normal supernovae (bolometric luminosity of 10^{40} – 10^{41} erg s⁻¹, effective temperature of $\sim 5 \times 10^3$ K, and timescale of 10–100 days) and shows a characteristic power-law decay, which may comprise a fraction of intermediate luminosity red transients (ILRTs) including AT 2017be. In addition to searching for the progenitor star in the archival data, we encourage X-ray follow-up observations of such ILRTs ~ 1 -10 yr after the collapse, targeting the fallback accretion disk.

Keywords: black holes—high energy astrophysics; transient sources—high energy astrophysics

1. INTRODUCTION

The main channel by which black holes (BHs) form is considered to be the gravitational collapse of massive stars. Numerical studies agree that a progenitor with a compact inner core can fail to revive the bounce shock (e.g. O'Connor & Ott 2011). These failed supernovae will be observed as massive stars suddenly vanishing upon BH formation, but their observational signatures are not completely known. Previous studies imply that the outcome depends on the star's angular momentum. Failed supernovae of stars with moderate or rapid rotation are expected to form accretion disks around the BHs, from which energetic transients are generated (Bodenheimer & Woosley 1983; Woosley 1993; MacFadyen & Woosley 1999; Kashiyaama & Quataert 2015; Kashiyaama et al. 2018; see also Quataert et al. 2019).

For the dominant slowly rotating case, the collapsing star can still leave behind a weak transient after BH

formation. During the protoneutron star phase before BH formation, neutrinos carry away a significant fraction of the energy of the core, around 10% of its rest mass energy (e.g., O'Connor & Ott 2013). This results in a decrease in the core's gravitational mass, and generates a sound pulse, which can eventually steepen into a shock and unbind the outer envelope of the star upon shock breakout (Nadezhin 1980; Lovegrove & Woosley 2013; Fernández et al. 2018; Coughlin et al. 2018a,b).

This work investigates the emission from mass ejection of blue supergiant (BSG) and Wolf-Rayet (WR) progenitors that fail to explode. As shown in Figure 1, we particularly consider emission from the interaction between the ejecta and a dense circumstellar medium (CSM), which is commonly introduced to explain Type II_n supernovae (e.g. Grasberg & Nadezhin 1986). In our case, where the ejecta mass is expected to be much lighter than normal supernovae, CSM interaction is still,

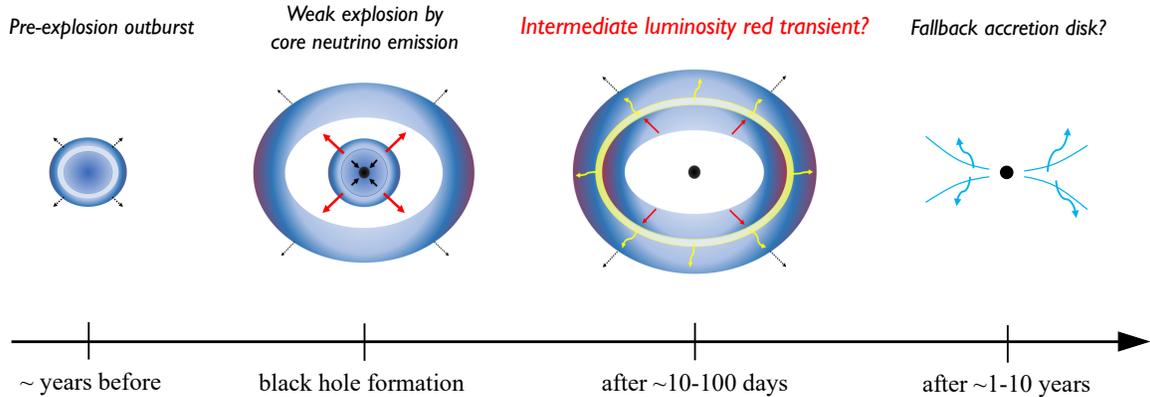

Figure 1. Schematic figure of the emission we consider in this work. The ejecta created upon BH formation collides with the CSM created from a mass eruption \sim years before core collapse. The kinetic energy of the ejecta is efficiently converted to radiation, being observable as intermediate luminosity red transients. The fallback of the outer layers of the envelope may form an accretion disk, that can be observable by X-rays 1–10 yr after core collapse.

and even more, important to efficiently convert the kinetic energy into radiation¹.

We find that the resulting emission is similar to what has been classified as intermediate luminosity red transients (ILRTs) observed in the previous decades (Kulkarni et al. 2007; Botticella et al. 2009; Smith et al. 2009; Berger et al. 2009; Bond et al. 2009; Cai et al. 2018; Jenson et al. 2019; Williams et al. 2020; Stritzinger et al. 2020). The origin of ILRTs is unknown, with several interpretations such as electron-capture supernovae or luminous blue variable-like mass eruptions. We propose an intriguing possibility that BH formation of massive stars can explain at least a fraction, if not all, of ILRTs.

This Letter is constructed as follows. In Section 2 we present the details of our emission model and demonstrate that an ILRT AT 2017be can be naturally explained with our model. In Section 3 we estimate the detectability of these signals by present and future optical surveys, and suggest ways to distinguish this from other transients.

2. OUR EMISSION MODEL

2.1. The Dense CSM

Past observations of Type IIn SNe found that the massive star’s final years can be dramatic, with mass-loss rates of $10^{-4} - 1 M_{\odot} \text{ yr}^{-1}$ (Kiewe et al. 2012; Taddia et al. 2013). Such mass loss may be common also for Type IIP supernovae ($\gtrsim 70\%$; Morozova et al. 2018), which comprises about half of all core-collapse supernovae. Although the detailed mechanism is unknown,

the huge mass loss implies energy injection greatly exceeding the Eddington rate, or instantaneous injection with timescales shorter than the outer envelope’s dynamical timescale.

Kuriyama & Shigeyama (2020) studied the CSM resulting from energy injection, for various progenitors while being agnostic of the injection model. A notable finding was that the inner part has a profile of roughly $\rho(r) \propto r^{-1.5}$, shallower than the commonly adopted wind profile ($\rho(r) \propto r^{-2}$). An example is in Figure 2, where we plot the density profile of a BSG erupting a mass of $0.02 M_{\odot}$ at 8.6 yr before core collapse. Motivated by this, we assume the CSM profile to be a power law $\rho(r) = qr^{-s}$, and take $s = 1.5$ as a representative value. The profile may be even shallower inwards due to the stronger gravitational pull from the central star. However, our assumption should not severely affect the dynamics of CSM interaction (given that the ejecta is heavier than the inner CSM), since the CSM mass is concentrated at where $s = 1.5$.

As neither the velocity nor mass-loss rate is constant, the standard parameterization of using wind velocity and mass-loss rate is not appropriate. Instead, we parameterize the dense CSM with its mass M_{CSM} , and time t_{CSM} between its eruption and core collapse. Since the outer edge of the CSM is $v_{\text{out}}t_{\text{CSM}}$, where v_{out} is the velocity of the outer edge, the CSM mass is related to q by $q \approx M_{\text{CSM}}(3-s)(v_{\text{out}}t_{\text{CSM}})^{s-3}/4\pi$. Because the CSM is created from the marginally bound part, v_{out} is of order the escape speed at the stellar surface. For $s = 1.5$,

$$q \sim 10^7 \text{ cgs} \left(\frac{M_{\text{CSM}}}{10^{-2} M_{\odot}} \right) \left(\frac{v_{\text{out}} t_{\text{CSM}}}{5 \times 10^{15} \text{ cm}} \right)^{-1.5}. \quad (1)$$

¹ For red supergiants, hydrogen recombination in the ejecta is expected to dominantly power the emission (Lovegrove & Woosley 2013), and a strong candidate is already found (Adams et al. 2017).

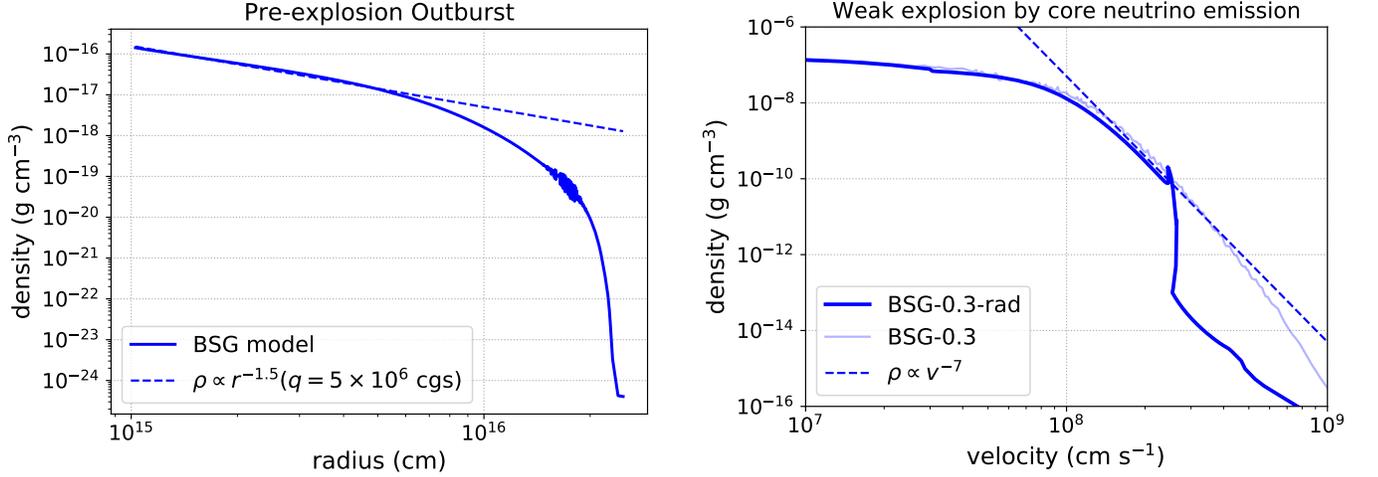

Figure 2. (Left panel): Example density profile at core collapse of the unbound CSM that was erupted by energy injection 8.6 yr before core collapse. For this calculation, energy of 3.0×10^{48} erg is injected in the base of the envelope for a timescale of 1.9×10^4 seconds, and the resulting total mass ejected is $1.9 \times 10^{-2} M_{\odot}$. (Right panel): Ejecta density profile for the “BSG–0.3” (light blue line, from the hydrodynamic simulation) and “BSG–0.3–rad” (dark blue line, from the radiation hydrodynamic simulation). We use the data at 10^5 s after core collapse, when the ejecta have become nearly homologous.

Kuriyama & Shigeyama (2020) finds for their BSG and WR (their WR-1) models $q \sim 10^6\text{--}10^9$ cgs and $v_{\text{out}} t_{\text{CSM}} \sim 5 \times 10^{15}$ cm.

The optical depth is given as a function of radius by $\tau(r) \approx \kappa q r^{1-s} / (s-1)$, where κ is the opacity. The photospheric radius where $\tau = 1$ is at $r_{\text{ph,CSM}} \approx [\kappa q / (s-1)]^{1/(s-1)}$. For $s = 1.5$,

$$r_{\text{ph,CSM}} \sim 2 \times 10^{13} \text{ cm} \left(\frac{\kappa}{0.2 \text{ cm}^2 \text{ g}^{-1}} \right)^2 \left(\frac{q}{10^7 \text{ cgs}} \right)^2. \quad (2)$$

For a low value of q that $r_{\text{ph,CSM}}$ is smaller than the progenitor’s radius, $r_{\text{ph,CSM}}$ would instead be at the progenitor’s surface.

2.2. Mass Ejection upon BH Formation

To model the mass ejection at the BH formation, we conduct hydrodynamical and radiation hydrodynamical calculations on the response of the pre-supernova star to core neutrino mass loss. The details of the simulations are in the Appendix. We summarize the adopted parameters and resulting ejecta in Table 1.

We find that the ejecta properties are roughly consistent with Fernández et al. (2018), with a double power-law density profile

$$\rho(r, t) = \begin{cases} t^{-3} [r/(gt)]^{-n} & (r/t > v_t, \text{ outer ejecta}), \\ t^{-3} (v_t/g)^{-n} [r/(tv_t)]^{-\delta} & (r/t < v_t, \text{ inner ejecta}), \end{cases} \quad (3)$$

where g and v_t are given by the ejecta mass M_{ej} and energy E_{ej} as

$$g = \left\{ \frac{1}{4\pi(n-\delta)} \frac{[2(5-\delta)(n-5)E_{\text{ej}}]^{(n-3)/2}}{[(3-\delta)(n-3)M_{\text{ej}}]^{(n-5)/2}} \right\}^{1/n}, \quad (4)$$

$$v_t = \left[\frac{2(5-\delta)(n-5)E_{\text{ej}}}{(3-\delta)(n-3)M_{\text{ej}}} \right]^{1/2}. \quad (5)$$

A notable point is that while overall we find from the hydrodynamical simulations that $n \approx 10$ (consistent with that of successful supernovae; Matzner & McKee 1999), we find from radiation hydrodynamical simulations (“BSG–0.3–rad” model) that $n \approx 7$, and that the truncation of the outer ejecta for $v > 2500 \text{ km s}^{-1}$. This is due to the leaking of radiation incorporated in the “BSG–0.3–rad” model, which prevents the radiative shock from pushing the ejecta to highest velocities upon shock breakout. Due to the truncation at the transition region between the inner and outer ejecta, a shallower profile of the outer ejecta is obtained. We thus adopt $n = 7$ as a representative value, although stronger shocks may realize a larger n close to the adiabatic case $n \approx 10$.

2.3. Emission from Ejecta-CSM Interaction

Collision of ejecta and CSM creates forward and reverse shocks that heat the ambient matter and generate photons via free-free emission. When it is the outer ejecta component (of $r/t > v_t$) that pushes the shocked region, the shock dynamics can be obtained from self-similar solutions (Chevalier 1982). This solution considers collision between a homologous ejecta of profile $\rho(r, t) = t^{-3}(r/gt)^{-n}$, and CSM of profile $\rho(r) = qr^{-s}$

Name	R_{cc}	M_{cc}	R_{in}	M_{in}	δM_G	$M_{\text{ej}} [M_{\odot}]$	$E_{\text{ej}} [\text{erg}]$	n

Table 1. Summary of the pre-supernova models and the resulting ejecta properties obtained from the simulations. The radius and mass at core collapse are R_{cc} and M_{cc} respectively. The inner boundary radius R_{in} and the enclosed mass $M_{r,\text{in}}$ are set at where the gravitational timescale is approximately equal to the neutrino emission timescale. δM_G is the gravitational mass loss by neutrinos. M_{ej} , E_{ej} , n are the ejecta mass, energy, and power-law index of the density profile of the outer ejecta respectively.

whose velocity is assumed to be negligible compared to the ejecta. The radius and the velocity of the contact discontinuity are obtained as

$$r_{\text{sh}}(t) = (\alpha g^n / q)^{1/(n-s)} t^{(n-3)/(n-s)}, \quad (6)$$

$$v_{\text{sh}}(t) = (n-3)/(n-s) \cdot r_{\text{sh}}/t, \quad (7)$$

where α is a constant determined by n , s , and the adiabatic index γ assumed to be constant of r and t .

At each shock’s rest frame, kinetic energy of matter crossing the shock becomes dissipated, with some fraction ϵ converted to radiation. As the two shocks propagate outwards, free-free emissivity by shock-heated matter is reduced. Thus at early phases when enough photons can be supplied $\epsilon \sim 1$, while at later phases ϵ should drop with time. The boundary is different for the two shocks, as the densities in the two shocks’ downstreams are usually much different (Chevalier 1982).

An analytical model of the bolometric light curve incorporating this time-evolving efficiency but neglecting photon diffusion was developed in Tsuna et al. (2019). The bolometric light curve is a sum of two broken power laws (corresponding to two shocks), with indices given by n and s as

$$L_{\text{bol}} \propto \begin{cases} t^{(-ns+2n+6s-15)/(n-s)} & (\epsilon \sim 1), \\ t^{(-2ns+3n+8s-15)/(n-s)} & (\epsilon < 1), \end{cases} \quad (8)$$

where the difference comes from the time dependence $\epsilon \propto t^{(-ns+n+2s)/(n-s)}$ when $\epsilon < 1$. We refer to Tsuna et al. (2019) for the full derivation of this luminosity.

Using this model we obtain bolometric light curves for various parameter sets of the ejecta and CSM, as shown in the top panels of Fig 3. We follow Tsuna et al. (2019) and set $\delta = 1$ and $\gamma = 1.2$. We define “BSG-*ExMytznvsu*” as a BSG model with $E_{\text{ej}} = 10^x$ erg, $M_{\text{CSM}} = 10^y M_{\odot}$, $t_{\text{CSM}} = z$ yr, $n = v$, $s = w$, and similarly for WR models. The value of q is obtained from equation 1, where we adopt $v_{\text{out}} = 10^2$ km s $^{-1}$ for BSG progenitors and $v_{\text{out}} = 10^3$ km s $^{-1}$ for WR progenitors. We also fix M_{ej} and adopt $0.1 M_{\odot}$ for BSGs and $10^{-3} M_{\odot}$ for WRs. We obtain the mean mass per

particle μ using the pre-supernova surface abundance listed in Fernández et al. (2018), and set $\mu = 0.846$ for BSGs and $\mu = 1.84$ for WRs.

For early times when $r_{\text{sh}} < r_{\text{ph,CSM}}$, photons from the shocked region diffuse through the CSM with timescale

$$t_{\text{diff}} \sim \int_{R_{\text{cc}}}^{r_{\text{ph,CSM}}} dr \frac{\tau(r)}{c}. \quad (9)$$

where R_{cc} is the progenitor radius at core collapse. The shock reaches $r_{\text{ph,CSM}}$ at time

$$t_{\text{ph}} \sim \left(\frac{\alpha g^n}{q} \right)^{-1/(n-3)} \left(\frac{\kappa q}{s-1} \right)^{(n-s)/[(s-1)(n-3)]}. \quad (10)$$

The analytical model is valid only for $t \gtrsim \min(t_{\text{diff}}, t_{\text{ph}})$ as it neglects diffusion. The regime where $t < \min(t_{\text{diff}}, t_{\text{ph}})$ is plotted in Fig 3 as dashed lines. As hydrogen is reduced from solar abundance for these progenitors, we assume $\kappa = 0.2$ cm 2 g $^{-1}$. The border is found to be $< \text{day}$ for our fiducial BSG (BSG:E48M-2t10n7s1.5) and WR (WR:E47M-2t1n7s1.5) cases.

We crudely estimate the temperature of the emission. For $t < t_{\text{ph}}$, the effective temperature is $T_{\text{eff}} \sim [L_{\text{bol}}/(4\pi r_{\text{ph,CSM}}^2 \sigma_{\text{SB}})]^{1/4}$, where σ_{SB} is the Stefan-Boltzmann constant. For $t > t_{\text{ph}}$, assuming the shocked region is optically thick, $T_{\text{eff}} \sim [L_{\text{bol}}/(4\pi r_{\text{sh}}^2 \sigma_{\text{SB}})]^{1/4}$. We show the temperature evolution in the bottom panels of Fig 3. We note that one cannot rely on the assumption $\kappa = 0.2$ cm 2 g $^{-1}$ at late phases when $T_{\text{eff}} \ll 5000$ K, since hydrogen starts to recombine and make the shocked region optically thin. Afterwards the spectrum for the late phase should deviate from a thermal one, and instead depend on the emission spectrum from the shocked region.

For the fiducial BSG:E48M-2t10n7s1.5 case, the luminosity and temperature scale with energy and time as

$$L_{\text{bol}} \sim 1 \times 10^{40} \text{ erg s}^{-1} \left(\frac{E_{\text{ej}}}{10^{48} \text{ erg}} \right)^{14/11} \left(\frac{t}{10 \text{ days}} \right)^{-5/11} \quad (11)$$

$$T_{\text{eff}} \sim 4 \times 10^3 \text{ K} \left(\frac{E_{\text{ej}}}{10^{48} \text{ erg}} \right)^{3/22} \left(\frac{t}{10 \text{ days}} \right)^{-21/44}. \quad (12)$$

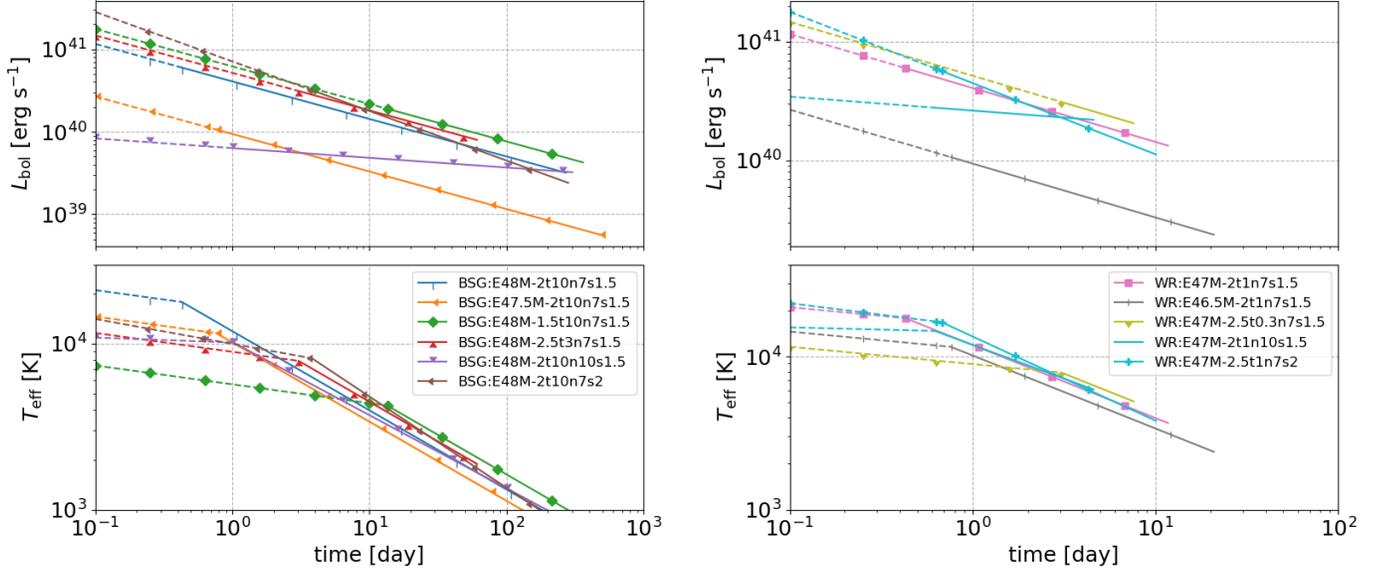

Figure 3. Light curves for BSG and WR progenitors using our semianalytical model. The power-law feature extends until when either the reverse shock reaches the inner ejecta (i.e. $v_{sh} = v_t$), or the shock reaches radius $v_{out}t_{CSM}$. The range shown as dashed lines is where diffusion can be important, which modifies the light curve from a power law.

The dependence of T_{eff} on the CSM parameters is not simple, as the power-law index can change at around 10 days. Despite uncertainties in the precise temperature and spectrum, we find that the features (timescale of 10–100 days, luminosity $\sim 10^{40}$ erg s^{-1} , temperature $\sim 5 \times 10^3$ K at 10 days for our fiducial model) are similar to ILRTs.

The power-law feature of the CSM interaction and the resultant light curve is valid until either (i) the reverse shock reaches the inner ejecta or (ii) the forward shock reaches the outer edge of the dense CSM. If either occurs, the dissipated kinetic energy and/or the radiation conversion efficiency drops, resulting in a cutoff in the light curve. Case (i) occurs when $v_{sh} \approx v_t$, at

$$t_{core} \approx \left[\sqrt{\frac{2(5-\delta)(n-5)(n-s)^2 E_{ej}}{(3-\delta)(n-3)^3 M_{ej}}} \left(\frac{\alpha g^n}{q} \right)^{-1/(n-s)} \right]^{\frac{n-s}{s-3}} \quad (13)$$

For the fiducial BSG:E48M-2t10n7s1.5 model,

$$t_{core} \sim 250 \text{ days} \left(\frac{E_{ej}}{10^{48} \text{ erg}} \right)^{-1/2} \left(\frac{M_{CSM}}{10^{-2} M_{\odot}} \right)^{-2/3} \left(\frac{t_{CSM}}{10 \text{ yr}} \right). \quad (14)$$

Case (ii) occurs when $r_{sh} = r_{out}$, at

$$t_{out} \sim (\alpha g^n / q)^{-1/(n-3)} r_{out}^{(n-s)/(n-3)} \quad (15)$$

For the fiducial BSG:E48M-2t10n7s1.5 model,

$$t_{out} \sim 270 \text{ days} \left(\frac{E_{ej}}{10^{48} \text{ erg}} \right)^{-1/2} \left(\frac{M_{CSM}}{10^{-2} M_{\odot}} \right)^{1/4} \left(\frac{t_{CSM}}{10 \text{ yr}} \right). \quad (16)$$

The two timescales may constrain t_{CSM} , which may give us some information on the progenitor’s activity just before core collapse.

2.4. Comparison with Observed ILRTs

Intriguingly, we may have already detected these events as ILRTs. We attempt to explain the observations of an ILRT AT 2017be (Adams et al. 2018) by our model with a BSG progenitor.

Previously Cai et al. (2018) claimed that this transient is likely to be an electron-capture supernova (ECSN). However, compared to the luminosity of a few $\times 10^{40}$ erg s^{-1} for AT 2017be, light curves from ECSN are predicted to have a plateau phase much brighter (of $\sim 10^{42}$ erg s^{-1}) lasting for 60-100 days (e.g. Tominaga et al. 2013; Moriya et al. 2014). We propose that a failed supernova, which has a much weaker explosion than ECSN, can reproduce the observations of AT 2017be.

We consider ejecta of mass $0.1 M_{\odot}$, energy 5.3×10^{47} erg, and $n = 7$ colliding with a CSM of $s = 1.5$. We set $q = 1.2 \times 10^8$ cgs, corresponding to M_{CSM} of

$$M_{CSM} \sim 1.6 \times 10^{-2} M_{\odot} \left(\frac{v_{out} t_{CSM}}{10^{15} \text{ cm}} \right)^{3/2} \quad (17)$$

Figure 4 shows the calculated light curve, with a comparison between that obtained in Cai et al. (2018) from the “hot component” of their two-component SED fit².

² The explosion date is assumed to be 15 days before the observed r-band peak (Cai et al. 2018).

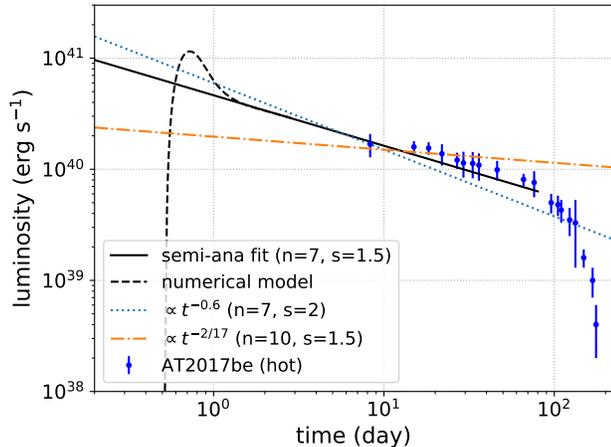

Figure 4. Fit of our failed BSG model to the luminosity evolution of the hot component of AT 2017be. The solid (dashed) line is from the semianalytical (numerical) light curve model in Tsuna et al. (2019). The power-law indices $n = 7$ and $s = 1.5$ match AT 2017be better than other sets of n and s in the plot (assuming a time independent ϵ) which predicts different power-law decays. Our model fit is stopped at 80 days, when the light curve is expected to display a cutoff (see the main text).

The solid black line is from the aforementioned analytical model, and the dashed black line is from a numerical model also introduced in Tsuna et al. (2019) that takes into account diffusion. The numerical curve is just meant to be a demonstration of the validity of the analytical model. The exact luminosity and timescale at peak is questionable due to the likely absence of the fastest component in the ejecta (see Section 2.2), which is not taken into account in the simulation. Nonetheless the late phases of the light curve that we compare here should be robust.

We find that the power-law feature of the observed light curve is naturally reproduced by our model, which predicts profiles of $n = 7$ and $s = 1.5$, while other power-law curves based on different ejecta and CSM profiles do not. The best-fit values of n and s matching with what we expect *a priori* gives support to our model.

The observed light curve shows a cutoff from ~ 100 days. We test if this cutoff can be explained by our model. Plugging the values we assumed for the ejecta and CSM into equations 13 and 15, we find $t_{\text{core}} \sim 80$ days and $t_{\text{out}} \sim 130$ days $(v_{\text{out}} t_{\text{CSM}} / 10^{15} \text{cm})^{11/8}$. Thus we can explain the cutoff at around 100 days if $v_{\text{out}} t_{\text{CSM}} \gtrsim 10^{15}$ cm. This constraint and v_{out} of order 100 km s^{-1} implies that the mass eruption occurred years before core collapse. This timescale is consistent with proposed mechanisms for mass eruption (Quataert & Shiode 2012; Moriya 2014; Smith & Arnett 2014).

In fact, if this mass eruption was due to energy injection from the interior of the star, the eruption itself can be luminous, with peak luminosity of 10^{40} – $10^{41} \text{ erg s}^{-1}$ (Kuriyama & Shigeyama 2020). This may have been detectable, as was the case for outbursts observed years before the terminal explosion in, e.g. SN 2006jc (Pastorello et al. 2007) and 2009ip (Mauerhan et al. 2013). Unfortunately pre-explosion images for AT 2017be are insufficient to test this or identify the progenitor star.

We compare our model to other ILRTs whose bolometric light curves were available, and find that AT 2019abn (Williams et al. 2020) can be consistent with our model. Its bolometric light curve shows a shallow power-law decay until ~ 50 days since discovery, followed by a nearly exponential cutoff. However, the power-law index ($\propto t^{-0.2}$ – $t^{-0.3}$, considering the uncertainty on the explosion epoch) is shallower than that predicted from $n = 7$ and $s = 1.5$ ($\propto t^{-0.45}$). This can be reconciled by adopting a shallower s of 0.3–0.9, or steeper n of 8–9. The latter requires a stronger explosion to preserve the faster part of the ejecta. Qualitatively, this may also explain AT 2019abn having an order of magnitude higher luminosity than AT 2017be. Although some ILRTs have identified progenitors that disfavor a BSG or WR origin (Prieto et al. 2008; Thompson et al. 2009; Kochanek 2011), our model may comprise a non-negligible fraction of ILRTs.

3. DISCUSSION

We estimate the local event rate of these events. If we use the local (successful) core collapse supernova rate $R_{\text{SN}} \sim 7 \times 10^{-5} \text{ Mpc}^{-3} \text{ yr}^{-1}$ (Li et al. 2011), the all-sky event rate R of failed supernovae within distance d is

$$R = f \times \frac{4\pi}{3} d^3 R_{\text{SN}} \sim 0.8 \text{ yr}^{-1} \left(\frac{f}{0.1} \right) \left(\frac{d}{30 \text{ Mpc}} \right)^3 \quad (18)$$

where f is the fraction of failed BSG/WR explosions among all core collapse.

Overall, the signal has luminosity of order $10^{40} \text{ erg s}^{-1}$ and time scale of order 10 days. For a blackbody emission of 5000 K and luminosity $10^{40} \text{ erg s}^{-1}$, the AB magnitude in the V and R bands are ≈ -11 mag. The Zwicky Transient Facility (ZTF; Bellm et al. 2019) and the Legacy Survey of Space and Time (LSST; Ivezić et al. 2008), with its survey having a sensitivity of 21 and 25 mag in these bands and cadence of 3 days, can in principle detect them out to $\sim 25 \text{ Mpc}$ and $\sim 100 \text{ Mpc}$ respectively.

Once a failed supernova candidate is found, it is important to distinguish this from other origins. A smoking gun may be the identification of the progenitor from archival data, as was done using archival Hubble Space

Telescope images in Gerke et al. (2015). This may be possible if the source is out to $\lesssim 30$ Mpc (Smartt 2009).

Another smoking gun may be X-ray emission, if a fraction of the outer envelope falls back to the BH with sufficient angular momentum to create an accretion disk. Fernández et al. (2018) claims from simple estimates that this can occur for BSG and WR progenitors. Failed supernovae from these progenitors not only have large fallback but also small M_{ej} , making them suitable targets to X-ray newborn BHs. Extrapolating the fallback rate obtained by Fernández et al. (2018) with the standard $\dot{M} \propto t^{-5/3}$ law, we find that the accretion rate persists above the Eddington rate of a $10M_{\odot}$ BH for 30 years for BSGs and 1 year for WRs. For an X-ray emission of Eddington luminosity from a $10M_{\odot}$ BH, the flux is $F_X \sim 1 \times 10^{-14} \text{ erg s}^{-1} (d/30 \text{ Mpc})^{-2}$, within reach for current X-ray telescopes once the ejecta become transparent to X-rays. The opacity to soft X-rays is mainly controlled by the photoelectric absorption by oxygen, whose cross section is $\sim 10^{-19} \text{ cm}^2$ at 1 keV for electrons in the K-shell. The oxygen column density of the ejecta is

$$N_O \sim \frac{X_O M_{\text{ej}} / 16m_p}{4\pi (v_{\text{ej}} t)^2} \\ \sim 10^{21} \text{ cm}^{-2} \left(\frac{X_O}{0.01} \right) \left(\frac{M_{\text{ej}}}{0.1M_{\odot}} \right) \left(\frac{v_{\text{ej}}}{10^3 \text{ km s}^{-1}} \right)^{-2} \left(\frac{t}{\text{yr}} \right)^{-2} \quad (19)$$

The oxygen mass fraction X_O is ~ 0.01 for BSGs which roughly follow the solar abundance, but higher

(~ 0.1) for WR stars. For BSG (WR) ejecta of $M_{\text{ej}} \sim 0.1M_{\odot}$, $v_{\text{ej}} \sim 10^3 \text{ km s}^{-1}$ ($M_{\text{ej}} \sim 10^{-3}M_{\odot}$, $v_{\text{ej}} \sim 3 \times 10^3 \text{ km s}^{-1}$), N_O becomes $\sim 10^{19} \text{ cm}^{-2}$ at 10 (1) yr, and afterwards the ejecta are transparent to X-rays. We thus encourage X-ray follow-up observations of ILRTs detected in the past decades, including AT 2017be.

When the ejecta is still optically thick to X-rays, injection of X-ray (and possible outflow from the accretion disk) can heat the ejecta. This may rebrighten the ejecta, analogous to what is proposed in Kisaka et al. (2016) in the context of neutron star mergers. The detailed emission will depend on when the fallback matter can create an accretion disk.)

ACKNOWLEDGMENTS

We thank the anonymous referees for important comments that improved this manuscript. We thank Rodrigo Fernández for providing us the pre-supernova stellar models, and also thank Kotaro Fujisawa and Yuki Takei for discussions. DT is supported by the Advanced Leading Graduate Course for Photon Science (ALPS) at the University of Tokyo. This work is also supported by JSPS KAKENHI Grant Numbers JP19J21578, JP17K14248, JP18H04573, 16H06341, 16K05287, 15H02082, 20K04010, MEXT, Japan.

APPENDIX

A. DETAILS OF THE SIMULATION OF MASS EJECTION UPON BH FORMATION

The hydrodynamical and radiation hydrodynamical calculations were done by Lagrangian codes developed in Ishii et al. (2018) and Kuriyama & Shigeyama (2020) respectively. For both of the two codes we use the same pre-collapse progenitor model as Fernández et al. (2018), and have modeled the neutrino mass loss by reducing the gravitational mass in the core by δM_G , which is varied between the most conservative ($\sim 0.2 M_{\odot}$) and most optimistic ($\sim 0.4 M_{\odot}$) cases adopted in Fernández et al. (2018). The outer boundary of the computational region is the progenitor's surface, and the inner boundary r_{in} is set to be the radius where the freefall timescale is equal to the timescale of neutrino emission τ_{ν} . This is justified by the fact that for matter at $r < r_{\text{in}}$, the freefall timescale is so short that it fails to react to the gravitational loss by neutrino emission and is swallowed by the BH, whereas the matter at $r > r_{\text{in}}$ has enough time to react. We determine r_{in} from the equation $\sqrt{r_{\text{in}}^3 / GM_{r,\text{in}}} = \tau_{\nu}$, where G is the gravitational constant and $M_{r,\text{in}}$ is the enclosed mass within r_{in} . Following Fernández et al. (2018), we set τ_{ν} to 3 s. We also follow Fernández et al. (2018) and include a prescription to remove the innermost cells that fall onto the core much faster than the local sound speed.
