Abstract

Sensitive millimeter wave diagnostics in magnetic confinement plasma fusion experiments need protection from gyrotron stray radiation in the plasma vessel. Modern Electron Cyclotron Resonance Heating (ECRH) systems take advantage of multi-frequency gyrotrons. This means that the frequency band of some millimeter-wave diagnostics contains more than one narrow-band gyrotron-frequency line, which needs to be effectively suppressed. A compact standard-waveguide notch filter based on coupled waveguide resonators with rectangular cross section is presented which can provide very high suppression of several gyrotron frequencies and has low insertion loss of the pass band.

Key words: Electron cyclotron resonance heating, magnetically confined fusion plasmas, millimeter wave diagnostics, notch filter.

1. Introduction

Modern multi-frequency megawatt-class gyrotrons can operate at several frequencies in the millimeter-wave range [1,2,3,4]. These frequencies correspond to the various transmission maxima of their single-disk chemical-vapor-deposition (CVD) diamond window. In recent years high-power gyrotrons became very attractive as sources for Electron Cyclotron Resonance Heating (ECRH) systems in thermonuclear fusion plasma experiments, since they allow for more flexibility with respect to the applied magnetic field in the magnetic confinement fusion devices [5]. Sensitive millimeter-wave diagnostic systems need protection against ECRH stray radiation [6]. When applying multi-frequency gyrotrons, more than one frequency must be suppressed. A specific problem concerning these filters is the frequency chirp of high-power gyrotrons due to cavity heating and expansion, specifically at the beginning of the pulse, which can range from tens to hundreds of MHz [7]. For ECRH systems applying many different gyrotrons, the notches need to be as wide as the specified accuracy provided by the gyrotron manufacturer, which is typically ± 250 MHz. These requirements are hard to fulfil with the available filter technology. Tunable coupled-cavity filters are difficult to be tuned for more than one specific stop band. Multi-frequency filters like optical Fabry Perot resonance filters can provide various, but only very narrow notches [6]. In principle it is possible to switch from one single frequency notch filter to another one, depending on the applied gyrotron frequency. However, for application of two gyrotron frequencies, it is preferable to have a single filter providing two stop bands. Two-frequency notch filters for the Electron Cyclotron Emission (ECE) diagnostic systems both at the ASDEX Upgrade tokamak experiment at IPP Garching and the W7-X stellarator at IPP Greifswald were successfully realized applying advanced waveguide Bragg reflectors [9]. In the present paper a much simpler and compact approach based on standard-waveguide resonators with rectangular cross section [10,11,12] is presented.

2. Filter Design

The goal of the present notch filter design is to reject the two frequencies of the ASDEX Upgrade and W7-X ECRH systems, which are 105 and 140 GHz. The filter should have no additional stop bands over the full waveguide band (D-band). This can be realized with in-waveguide resonators as described in [10], i.e. standard rectangular waveguides with symmetric steps in the width. In this case there is no coupling to TM modes and an incident fundamental waveguide $TE_{1,0}$ fundamental mode only couples to $TE_{2-m+1,0}$ providing a very limited mode spectrum. To calculate the step-type coupling a mode matching formalism [10] is applied, taking into account both propagating and evanescent modes. As an example, Fig. 1 shows the coupling of a symmetric step from fundamental waveguide with width $a = 1.651$ mm (WR-06) to $a_r = 7.0$ mm and with a constant height $b = 0.826$ mm. Due to symmetry, the incident TE_{10} mode only couples to TE_{m0} modes with odd $m=3,5,7,\dots$.

A resonant cavity at both 105 and 140 GHz can be created by a stepped waveguide where the length l_r of the step corresponds to approximately half of the wavelength for the TE_{30} mode at 105 GHz and the TE_{50} mode at 140 GHz. The optimum dimensions of the waveguide cavity can be determined by calculating the power transmission at both frequencies as a function of both the width a_r and the length l_r of a single cavity. Fig. 2 shows the transmission minima at both frequencies. The point where both domains meet gives the correct dimension of the desired cavity.

Fig. 3 shows the calculated frequency characteristic of the resonator with only two notches over the full D-Band. The modal amplitude distributions along the waveguide circuit at the 105 and 140 GHz resonances are plotted in Fig. 4.

As can be seen from Fig. 4, there exist resonant mode mixtures with the dominant modes being TE_{30} at 105 GHz and TE_{50} at 140 GHz, but also evanescent TE_{m0} cutoff modes have to be taken into account in the generalized scattering matrix calculations. The resonant electric field distributions over the horizontal waveguide cross section at the two resonances are plotted in Fig. 5.

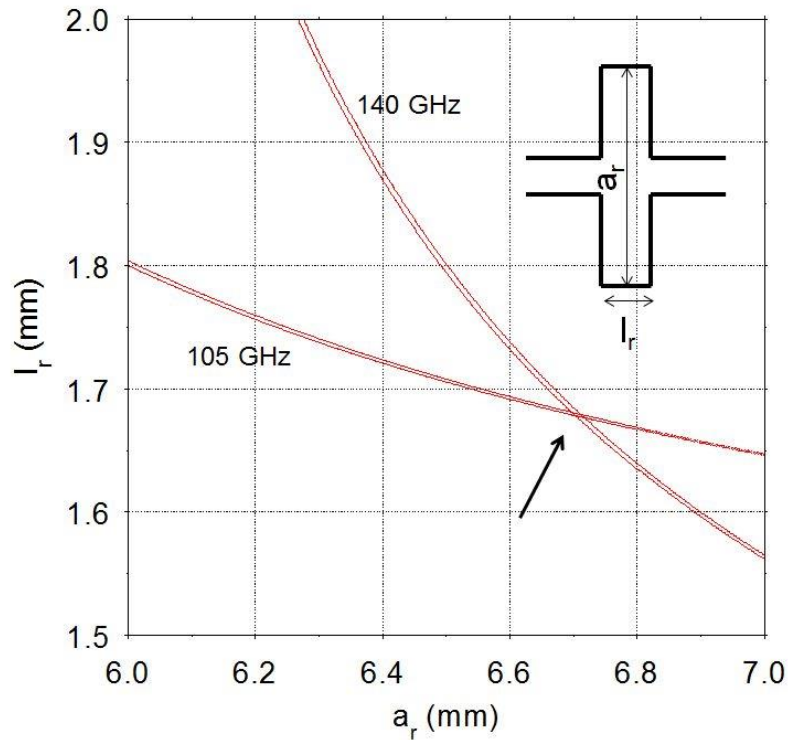

Fig. 2 Calculated transmitted power as a function of width a_r and length l_r of the waveguide cavity. The red lines mark the domains where the transmitted power is below -23 dB. The arrow marks the point where the minima for both frequencies meet and therefore gives the correct dimensions of the desired cavity ($a_r = 6.72$ mm, $b_r = 0.826$ mm, $l_r = 1.64$ mm).

Fig. 3 Calculated transmission of the TE_{10} -mode of a single resonator with the dimensions $a_r = 6.72$ mm, $b_r = 0.826$ mm, $l_r = 1.68$ mm.

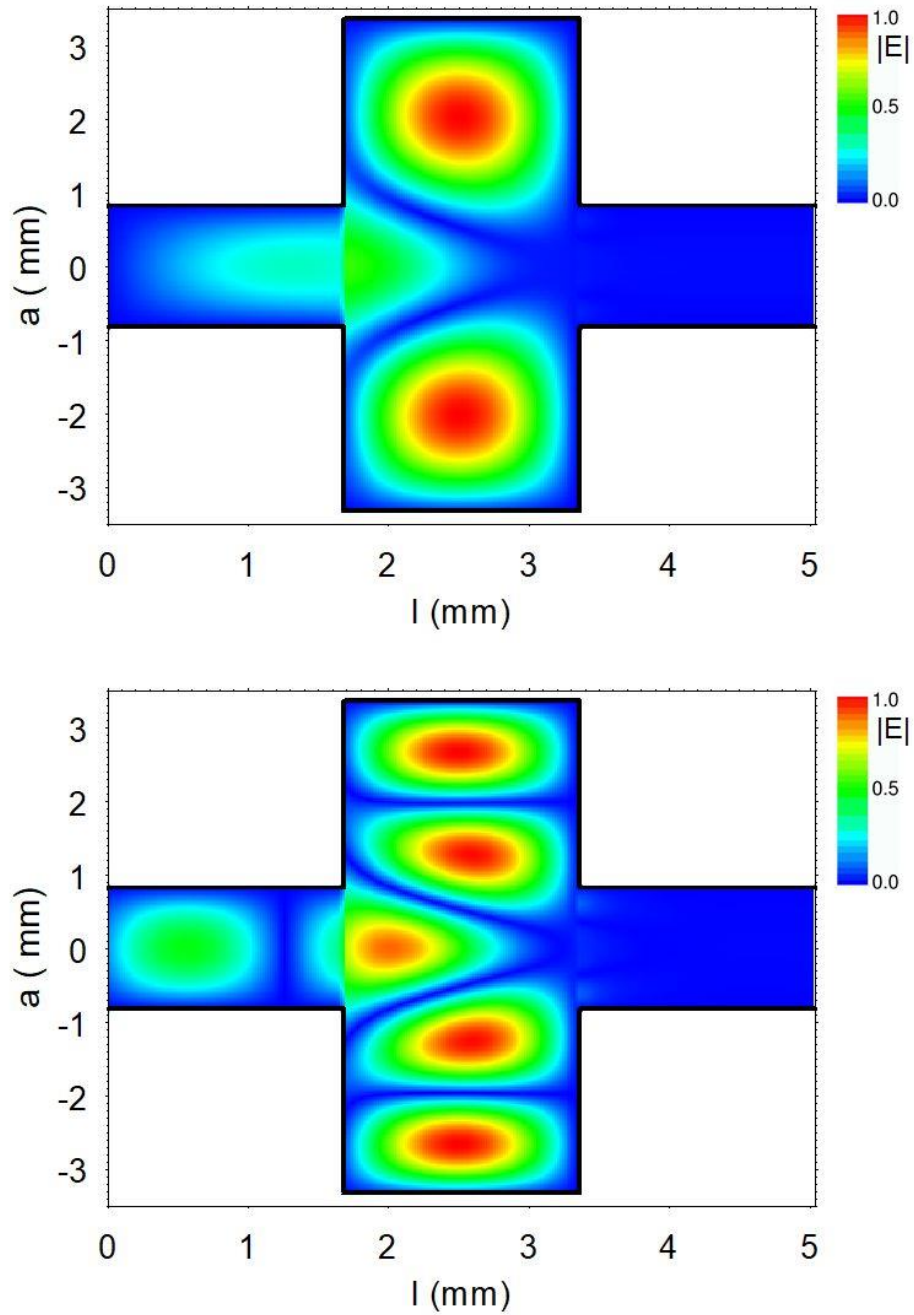

Fig. 5 Calculated electric field distribution at the resonance frequencies 105 GHz (top) and 140 GHz (bottom).

3. Multi-Cavity Filter

The signal suppression of the two stop bands can be further increased by combining several cavities. Figure 6 shows the geometry of a filter with 5 resonators, where each cavity has the same dimensions as the single cavity investigated in Section 2. Figure 7 presents a comparison of the frequency characteristics of filters with a different number of cavities. With 5 cavities, the theoretical notch depth at both resonant frequencies (105 and 140 GHz) is below -120 dB.

Fig. 7 Comparison of the calculated transmission of the TE_{10} -mode of a single ($n = 1$) up to a chain of $n = 5$ resonators with the dimensions $a_r = 6.72$ mm, $b_r = 0.826$ mm, $l_r = 1.68$ mm.

4. Measurements

A 5-cavity filter was fabricated in split-block technology and tested. The filter geometry has been cut out of a sheet metal plate with thickness 0.826 mm, corresponding to the height of a standard WR-06 waveguide. The plate has been sandwiched between two metallic blocks to form the filter geometry. Fig. 8 shows photos of the filter and its separate parts. The material is brass. First measurements with the assembled notch filter were performed in the frequency band 117.5-150 GHz using a GYCOM GGBWO-78/178 BWO as source and an ELMIKA D-band detector diode as receiver (Fig. 9). The first measurement revealed a higher insertion loss of about 10 dB compared to theory as well as a broadened and downshifted upper notch around 140 GHz (red curve). After polishing and reassembling of the filter parts, the insertion loss was reduced by 5 dB and the width of the stop band narrowed (green curve). To further reduce the surface losses and improve the contact between the center plate and both upper and lower block, all the parts were gold plated and assembled again. The measurement with the gold plated filter is given by the black curve, which is again closer to the theoretical values (blue curve). Since the dynamic range of these measurements was only about -40 dB, we performed additional measurements at IGVP Stuttgart using an ABmm 8-350 Vector Network Analyzer (VNA) in the frequency range from 96 to 156 GHz and at KIT Karlsruhe using a PNA N5222B VNA from 135 to 170 GHz. These measurements are shown in Figure 10 together with the theoretical frequency characteristic. Both measurements are in excellent agreement and their frequency dependence compares well with the calculation. The dynamic range of the ABmm VNA is limited to about -60 dB around 140 GHz where its background noise dominates, while the dynamic range of the KIT-measurement was -80 dB. Half of the conductivity of ideal gold was assumed in the calculation to cope for surface roughness. However, the measured insertion loss is still somewhat higher than calculated (3-4 dB in the range 110-140 GHz and about 2 dB between 140 and 170 GHz). This is most probably due to non-perfect contact between the two blocks and the center sheet over the common surface in this split block construction. Figures 11 and 12 give more details in the two rejection bands around 105 and 140 GHz. The frequency range of all 8 ASDEX Upgrade gyrotrons, including their frequency chirps and drifts during the pulse, is indicated by the dashed lines. All gyrotron frequencies are within the stop bands.

Summary

A compact rectangular waveguide two-frequency notch filter has been designed, fabricated and tested. The filter provides suppression of two narrow frequency intervals in the D-band. This could be realized by introducing symmetric steps in the width of a standard WR-06 waveguide. The measured notch depth is about -60 dB at 105 GHz and -80 dB at 140 GHz. No additional tuning was required.

Acknowledgement

The authors would like thank H. Schütz and G. Grünwald from IPP Garching for support with the construction, assembling and measurement of the notch filter. We are also indebted to B. Graf and M. Father from IPP for helpful discussions and the precise manufacturing.
