Revised: 5 July 2021 – Accepted: 7 July 2021 – Published: 25 August 2021

**Abstract.** The African Tropics are hotspots of modern-day land use change and are, at the same time, of great relevance for the cycling of carbon (C) and nutrients between plants, soils, and the atmosphere. However, the consequences of land conversion on biogeochemical cycles are still largely unknown as they are not studied in a landscape context that defines the geomorphic, geochemical, and pedological framework in which biological processes take place. Thus, the response of tropical soils to disturbance by erosion and land conversion is one of the great uncertainties in assessing the carrying capacity of tropical landscapes to grow food for future generations and in predicting greenhouse gas fluxes from soils to the atmosphere and, hence, future earth system dynamics.

Here we describe version 1.0 of an open-access database created as part of the project “Tropical soil organic carbon dynamics along erosional disturbance gradients in relation to variability in soil geochemistry and land use” (TropSOC). TropSOC v1.0 (Doetterl et al., 2021, <https://doi.org/10.5880/figeo.2021.009>) contains spatially and temporally explicit data on soil, vegetation, environmental properties, and land management collected from 136 pristine tropical forest and cropland plots between 2017 and 2020 as part of monitoring and sampling campaigns in the eastern Congo Basin and the East African Rift Valley system. The results of several laboratory experiments focusing on soil microbial activity, C cycling, and C stabilization in soils complement the dataset to deliver one of the first landscape-scale datasets to study the linkages and feedbacks between geology, geomorphology, and pedogenesis as controls on biogeochemical cycles in a variety of natural and managed systems in the African Tropics.

The hierarchical and interdisciplinary structure of the TropSOC database allows linking of a wide range of parameters and observations on soil and vegetation dynamics along with other supporting information that may also be measured at one or more levels of the hierarchy. TropSOC’s data mark a significant contribution to improve our understanding of the fate of biogeochemical cycles in dynamic and diverse tropical African (agro-)ecosystems. TropSOC v1.0 can be accessed through the Supplement provided as part of this paper or as a separate download via the websites of the Congo Biogeochemistry Observatory and GFZ Data Services where version updates to the database will be provided as the project develops.

## 1 Rationale for project TropSOC

### 1.1 Changing tropical environments in Africa

Tropical ecosystems provide many services of global importance. Tropical forests are among the largest terrestrial carbon (C) reservoirs and show some of the highest levels of biodiversity (Losos and Leigh, 2004; Pan et al., 2011). At the same time, tropical landscapes are among the most dynamic regions worldwide and hotspots of modern day land use change (Hansen et al., 2013) as they have to provide food for some of the poorest yet fastest growing populations on the planet. In particular, the African continent is facing huge environmental and societal challenges with a projected population growth of 400 % by the end of this century (Gerland et al., 2014), much of it happening in (sub-)tropical sub-Saharan Africa. In consequence, forested landscapes in tropical Africa are currently facing unprecedented levels of land conversion and land degradation, accompanied by decreasing soil fertility (UNESCO and WHC, 2010). At the same time, unlike other tropical regions of the world where deforestation is driven by the extension of commodity plantations and commercial logging, much of the deforestation in tropical African countries is driven by smallholder farms that apply slash and burn practices for subsistence farming with little alternatives to provide food for their families (Curtis et al., 2018; Tyukavina et al., 2018). As a result, deforestation and soil degradation have accelerated greatly since the second half of the 20th century, with soil erosion in particular, emerging as the main driver of soil degradation.

Today, erosion rates of tropical agricultural land globally are estimated at approx. 10.4 billion tons of soil per year and 0.2 billion tons of C per year. Tropical agricultural soil erosion therefore represents about half of the annual agricultural

erosion globally while only representing about one third of global cropland (Doetterl et al., 2012). An exemplary region to observe the consequences of land use change on soil resources and biogeochemical cycles in the tropical African regional context is the African Great Lakes region and, in particular, East African Rift Valley system along the borders between the Democratic Republic of the Congo (DRC), Burundi, Rwanda, and Uganda.

The region is a model for the complex interplay of socioeconomic factors and their consequences for environmental systems in the tropics. One of the highest human fertility rates globally (e.g., recent estimates for the last decade range from 7.3 to 7.7 children per woman in the province of South Kivu, eastern DRC) (Dumbaugh et al., 2018) is leading to massive population growth in the region, largely relying on local food and energy resources. Ridden by conflict and open warfare in the 1990s and early 2000s, population growth in the region is further aggravated by refugees from remote areas settling in nearby safer, larger cities in the region (Kujirakinja et al., 2010). Consequently, massive deforestation of upland forests for firewood and cropland expansion is taking place (Hansen et al., 2013), leading to large erosional soil fluxes and consequential soil degradation threatening soil quality (Karamage et al., 2016). Once conversion to agricultural land has taken place, soil conservation measures could counteract the loss of soil quality (Veldkamp et al., 2020). However, these measures are rare in the eastern Congo Basin due to the poverty of subsistence farmers, socioeconomic instability, and a lack of governmental intervention (Heri-Kazi Bisimwa and Biolders, 2020). Soil tillage and harvesting further degrade the nutrient-containing litter and topsoil layers. Consequently, fields often have to be abandoned after only a decade of use and recover poorly (Carreño-Rocabado et al.,

2016; Ewel et al., 1991; Hattori et al., 2019; Heinrich et al., 2020; Kleinman et al., 1996; Lawrence et al., 2010).

## 1.2 Tropical soils responding to disturbance

With the expansion of cropland into forested landscapes, soil erosion rates are expected to continue to increase. Soil erosion will undoubtedly have an impact on biogeochemical cycles and will change the input, storage, and exchange of C between soils and the atmosphere, as well as the flux of nutrients between plants and soils in tropical systems in the region. To understand how tropical soils and ecosystems respond to erosional disturbance, it is necessary to consider the combined effects of climate, geology, topography, soil formation, biological processes, and human disturbance. To date, no study on the interrelationship of these controls on biogeochemical cycles has been carried out in tropical ecosystems. However, studies carried out in other regions have shown that controls on soil C dynamics, for example, are highly interlinked (Doetterl et al., 2015; Hobbey and Wilson, 2016; Nadeu et al., 2015).

Soil redistribution as a consequence of erosion also changes the functionality of landscape units. For example, soil degradation on hillslopes is matched by a buildup of sediment deposits in valley bottoms where C and nutrient-rich soil can be rapidly buried in subsoils under new sediments. While this consequence of deforestation can lead to an increase in the residence time of C due to slower microbial C turnover in buried soil (Van Oost et al., 2007; Doetterl et al., 2012; Alcántara et al., 2017), important nutrients are now lost to plants, leading to a decrease in biomass productivity (Veldkamp et al., 2020) but also to a general degradation of tropical forest soils, lowering also microbial activity in soils (Sahani and Behera, 2001). Soil redistribution is also known to change the temporal and spatial patterns of soil weathering and affects C stabilization. In agricultural systems, the effects of this pressure can be observed very clearly: erosion removes weathered soil from eroding slopes but also brings the soil weathering front into closer contact with the C cycle (which occurs primarily in topsoils), thereby affecting carbon, nitrogen, and phosphorus (CNP) cycling and the stabilization of C with minerals in these systems (e.g., Berhe et al., 2012; Park et al., 2014; Doetterl et al., 2016).

Concerning feedbacks on biogeochemical cycles between soil weathering, erosion will differ significantly not only between natural and disturbed systems but also between systems with differing soil mineral reactivity. Recent advances have shown that mineral reactivity, constrained predominantly by soil weathering and the mineralogy of the soil parent material, has direct control over soil organic carbon, with climate exerting only indirect control through its impact on biogeochemical processes and matter fluxes (Doetterl et al., 2015; Tang and Riley, 2015). However, the exact effects of mineralogy on the temperature sensitivity of microbial decomposer communities and the primary productiv-

ity of ecosystems have, to date, not been constrained (Hahm et al., 2014; Tang and Riley, 2015).

## 1.3 Importance and outlook of research on the future of tropical biogeochemical cycles

Tropical Africa is expected to experience great changes to both soil biogeochemical cycling and ecosystem-level carbon (C) fluxes between soil, plants, and the atmosphere with unknown consequences for biogeochemical cycles. Despite decades of recognizing their importance, tropical soils remain among the least studied in the world (Mohr and van Baren, 1954; Mohr et al., 1972; Ssali et al., 1986; Juo and Franzluebbers, 2003). Although a more complete understanding of soil–plant coupling in tropical environments is critical, most of our process understanding of biogeochemical cycling between plant and soil is still derived from temperate regions. However, due to differences in their environmental setting and soil forming history, many tropical soil systems will likely react very differently to soil disturbance and land conversion than temperate soil systems. For example, temperate ecosystems can differ fundamentally in the way nutrients cycle and in the dominating and limiting factors for plant growth (Du et al., 2020). In contrast to soils in the temperate zone, long-lasting chemical weathering has led to a massive depletion of mineral nutrients from soils in many tropical systems, although the remaining available nutrients are very efficiently recycled in natural tropical biospheres (Walker and Syers, 1976; Vitousek, 1984). Hence, any loss of nutrients is therefore a critical disturbance with direct effects on the functioning of tropical (agro-)ecosystems. Recent studies highlight the importance of soil degradation and the change in chemical soil properties that follows land conversion on plant communities in tropical systems (Bauters et al., 2021), organic matter turnover by microbial decomposers (Bukombe et al., 2021), and the stabilization of C and nutrients in soil of varying mineralogical properties (Reichenbach et al., 2021).

Improving our process understanding of the coupling between soil biogeochemistry and plant responses in the context of tropical land use changes will help to better constrain and define plant–soil interactions in ecosystem and land surface models. Furthermore, insight into plant–soil interactions can help to better inform policy makers and stakeholders in improving land management practices.

## 1.4 Objectives and framework

In the following we aim at providing an overview of the data collected by project TropSOC (Tropical soil organic carbon dynamics along erosional disturbance gradients in relation to variability in soil geochemistry and land use) which is now available to the research community as an open-access database. We give a brief description of the project's design before elaborating on the structure of the database and

its content. Note that beyond the overview information presented here, more details on methods and sampling designs for each assessed parameter are explained in greater detail in the Supplement accompanying the paper and the database.

The main objective of project TropSOC was to develop a mechanistic understanding of plant and microbial process responses to changing soil properties in the African Tropics, exemplified along land use and erosional and soil geochemical gradients studied in the Congo and the Albertine Rift. Trying to understand biogeochemical cycling affected by human activities in tropical (agro-)ecosystems as a whole, TropSOC had two main foci:

- i. investigate how nutrient fluxes and organic matter allocation between tropical soils and plants differ in relation to the controlling factors of geochemistry, topography, and land use;
- ii. investigate how the geochemistry of soils and their parent material control, interact with, or mediate the severity of erosional disturbance on C cycling in tropical soils.

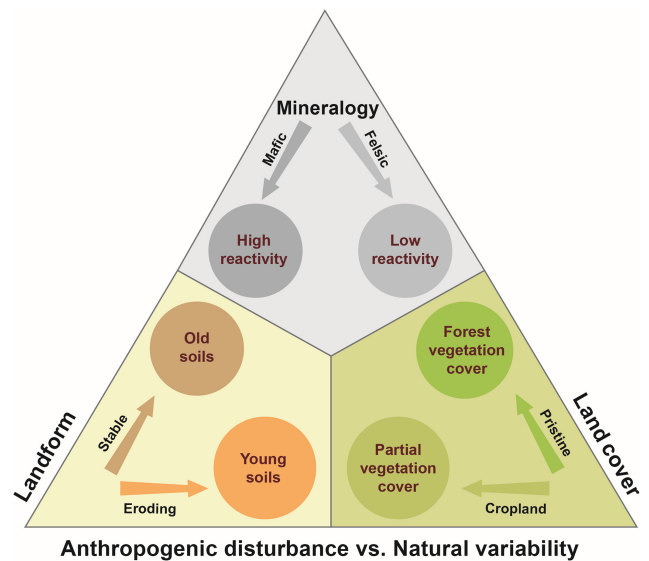

In order to address these objectives, project TropSOC investigates effects on tropical soil biogeochemical cycling and biological responses to variation in soil and environmental properties along three main vectors (Fig. 1): (i) mineralogy of parent material, since it may drive the geochemical features of developed soils which control soil fertility and the potential of soils to stabilize organic matter and nutrients; (ii) landform, since topography may influence water and soil fluxes, particularly erosional soil loss on slopes and soil deposition in valleys; and (iii) vegetation and land cover, since it may control the input to and extraction of organic matter from soil and respond to variation in soil properties and hydrology, as well as mediate the impact of rainfall to induce soil erosion.

Conducted in one of the hotspots of global change – in the Central African Congo Basin and African Great Lakes region – the database described here is the foundation for several papers published as a part of the 2021 special issue *Tropical biogeochemistry of soils in the Congo Basin and the African Great Lakes region* in SOIL Journal (Bukombe et al., 2021; Summerauer et al., 2021; Reichenbach et al., 2021; Wilken et al., 2021).

## 2 Study and sampling design

### 2.1 Study area – climate, topography, land use

The study area of TropSOC is located in the eastern part of the Democratic Republic of the Congo, Rwanda, and Uganda, in the border region between the Congo and the Nile Basin (Fig. 2). It is largely understudied (Schimel et al., 2015) despite its great significance for the global climate system (Jobbágy and Jackson, 2000; Amundson et al., 2015)

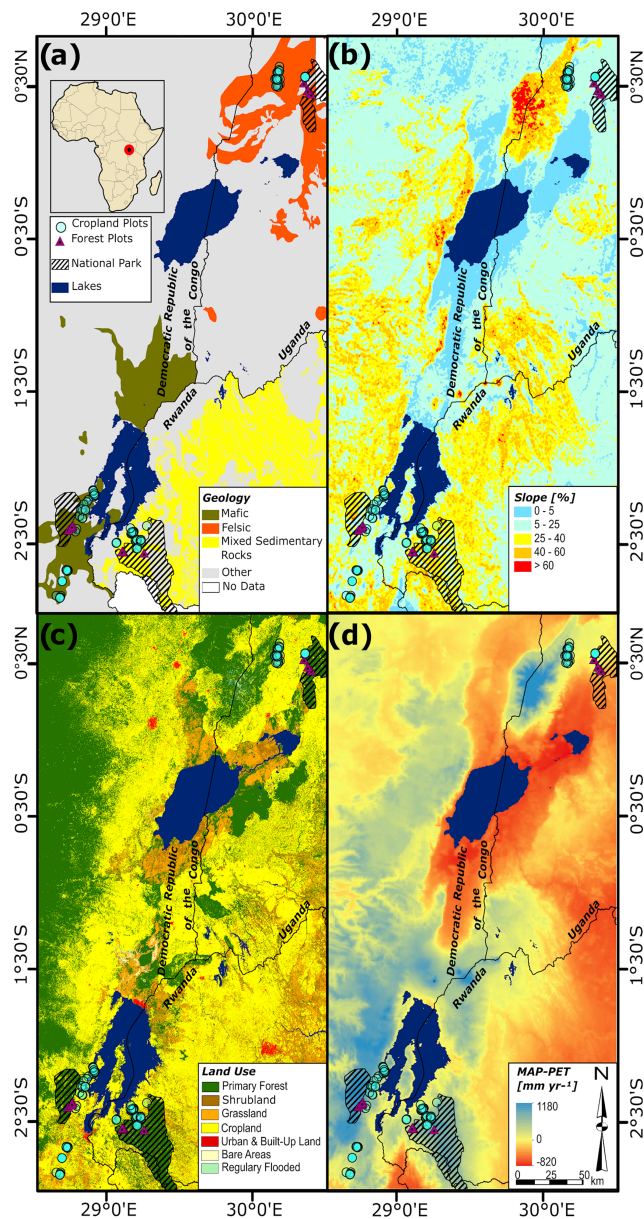

**Figure 1.** Factorial design of project TropSOC studying biogeochemical cycles in Central African tropical forest and agricultural landscapes in relation to mineralogy, landform, and land cover types.

and is being confronted with rapid land conversion and forest degradation (Hansen et al., 2013). The climate of the study region is classified as tropical humid with weak monsoonal dynamics (Köppen Af–Am) and mean annual temperatures (MAT) ranging between 15.3 and 19.3 °C and mean annual precipitation (MAP) between 1498 and 1924 mm (Fick and Hijmans, 2017) with high potential erosivity (Fenta et al., 2017) (Fig. 2d).

As a part of the East African Rift mountain system, the active tectonism within the study region produced a hilly, patchy landscape with steep slopes up to 60 % and soil parent material ranging from volcanic ashes to mafic and felsic magmatic rocks, as well as a sedimentary rocks of varying geochemistry and texture (Schlüter and Trauth, 2006) (Fig. 2a, b).

The study area is dominated by agricultural land use, with larger patches of protected, old-growth closed-canopy forest in highland areas (Fig. 2c). Typical crops planted for subsistence farming are rotations of cassava (*Manihot esculenta*), maize (*Zea mays*), and a variety of legumes and vegetables. The dominant vegetation in all studied forests of the region is characterized as tropical mountain forest (Verhegghen et al., 2012; van Breugel et al., 2015). Note that while forest vegetation is thought to be largely spared from direct disturbance by human activities, large mammal populations (i.e., African forest elephants, great apes) became extinct or largely reduced due to hunting during the 20th century resulting in a massive increase in understory.

**Figure 2.** Overview of the study region with respect to major investigated factors: soil parent material geology and geochemical regions (a), slope steepness (b), land use (c), and climate (d) (data sources: Farr et al., 2007; Fick and Hijmans, 2017; Friedl et al., 2013; Dewitte et al., 2013; Dressée et al., 1949; Trabucco and Zomer et al., 2018; Verdoht and Van Ranst, 2003).

## 2.2 Study area – geochemistry and soil types

Within the study area three regions each representing a geochemically different parent material for soil formation were determined. The first region (Fig. 2a) is predominantly situated on mafic magmatic rocks, typically mafic alkali basalts (Schlüter and Trauth, 2006), resulting from extinct (Mount Kahuzi) and active (Mount Nyiragongo) volcanic activities between the cities of Bukavu and Goma, Kivu, DRC. The

second region is situated on felsic magmatic and metamorphic rocks typically consisting of gneissic granites (Schlüter and Trauth, 2006) near the city of Fort Portal on the foothills of the Rwenzori Mountains, Uganda. The third region is situated on a mixture of sedimentary rocks of varying geochemistry consisting of alternate layers of quartz-rich sandstone, siltstone, and dark clay schists (Schlüter and Trauth, 2006) and spread across the western province of Rwanda in and around the district of Rusizi.

The dominant soil types of the study region are various forms of deeply weathered tropical soils (FAO, 2014). Potential ash deposition through the region's active volcanism occurs frequently, re-fertilizing soils to various degrees. Following World Reference Base (WRB) soil classification (IUSS, 2014), soils in the mafic region can be described as umbric, vetic, and geric Ferralsol and ferralic vetic Nitisol. Soils in the mixed sedimentary rock region and the felsic region can be described as geric and vetic Ferralsol. Soils in valley bottoms can locally show gleyic features, where the dominating soil types are variations of fluvic Gleysol.

Several striking differences in the elemental composition of the three parent materials can be noted. In the mafic region, bedrock is characterized by high iron (Fe) and aluminum (Al) content, as well as a comparably high content of rock-derived nutrients such as base cations and phosphorus (P). The felsic and sedimentary rock regions are characterized by lower contents of Fe and Al, by lower rock-derived nutrient contents, and by higher Si content (Fig. 3). A specific feature of the sedimentary site is the presence of fossil organic C in the parent material of soils ranging between 1.29 % and 4.03 % C. Fossil organic C in these sediments is further characterized by a high C : N ratio (mean  $\pm$  standard deviation:  $153.9 \pm 68.5$ ), depleted in N and free of <sup>14</sup>C (due to the high age of sedimentary rock formation). The elemental composition of soils at a stable landscape position between the three regions retains the geochemical features of its parent material to some degree and illustrates the process of enrichment of metal oxy-hydroxides and the depletion of silica as a consequence of weathering. Generally, differences in the elemental concentrations between the three regions are less pronounced in soil (Fig. 4) compared to differences in parent material (Fig. 3). Remarkably, levels of rock-derived nutrients in soil, while overall depleted compared to the parent material, are comparably similar, potentially indicating biological mechanisms that protect these important nutrients in the plant–soil system against a general trend of leaching and depletion, typical for weathered, old, and nutrient-poor tropical soils (Grau et al., 2017 and references therein).

In summary, the study region provides a unique combination of (i) near-pristine forest and agricultural land, (ii) steep terrain and heavy tropical precipitation with high erosion potential, and (iii) geologically diverse parent material for soil formation. These factors make the study region ideal for identifying the importance of various controls on tropical soil biogeochemical cycles.

## 2.3 Overview of plots and sampling design

Plots were established along geomorphic gradients in old-growth closed-canopy forest, as well as in cropland, in all three geochemical regions. Field campaigns to collect soil and plant samples at 136 forest and cropland plots along slope gradients (catena and stratified random approaches) and additionally within several cropped nearby micro-catchments were carried out between March 2018 and July 2020. A detailed description on data quantity and quality can be found in the metadata files accompanying the database and are briefly described in Sect. 4.1 of this publication. In order to cover potentially stable, eroding, and depositional landforms, topographic positions of plots ranged from plateaus (slope < 5 %), over two slope positions (slopes between 9 % and 60 %) to valley positions (slopes < 5 %) (Table 1).

## 2.4 Sampling design forest

### 2.4.1 Forest plot installation

Sampling in forests followed a strict catena approach, and plots were established following an international, standardized protocol for tropical regions (Phillips et al., 2016). Within each geochemical region, three plots covered by old-growth closed-canopy tropical forest vegetation (forest that developed a complex structure characterized by large, living and dead trees) were established from February to June 2018 per topographic position as field replicates representing an area of 40 m × 40 m per plot were established. Each plot was subdivided in four 20 m × 20 m subplots, and a total of 36 forest plots were established this way (four topographic positions with three replicate plots each in three geochemical regions). Note that three plots in the mafic region had to be relocated due to safety reasons after the sampling period. For an overview of forest plot sampling design, see Fig. 5a.

### 2.4.2 Sampling mineral and organic soil layers

At the time of plot installation, four replicate soil cores per plot (one in each subplot) were taken in a depth-explicit way in 10 cm increments up to 1 m soil depth and combined as composites per plot. In addition, one soil profile pit was dug to a depth of 100 cm in the center of one of three replicate plots (Fig. 5) per topographic position in each geochemical region. These soil pits were dug and described according to FAO guidelines (FAO, 2006).

Leaf litter (L horizon) and partially decomposed organic material in O horizons were sampled at eight points along the border and in the center of each forest plot (Fig. 5a). At each sampling point, the thickness of the L and O horizon layer was measured with a ruler and then sampled within a 5 cm × 5 cm square. When the litter layer was too thin (= no closed coverage of forest floor with litter), the sampling square was expanded to a 10 cm × 10 cm to retrieve

enough sample material. The nine samples of each layer per plot were combined to one composite sample.

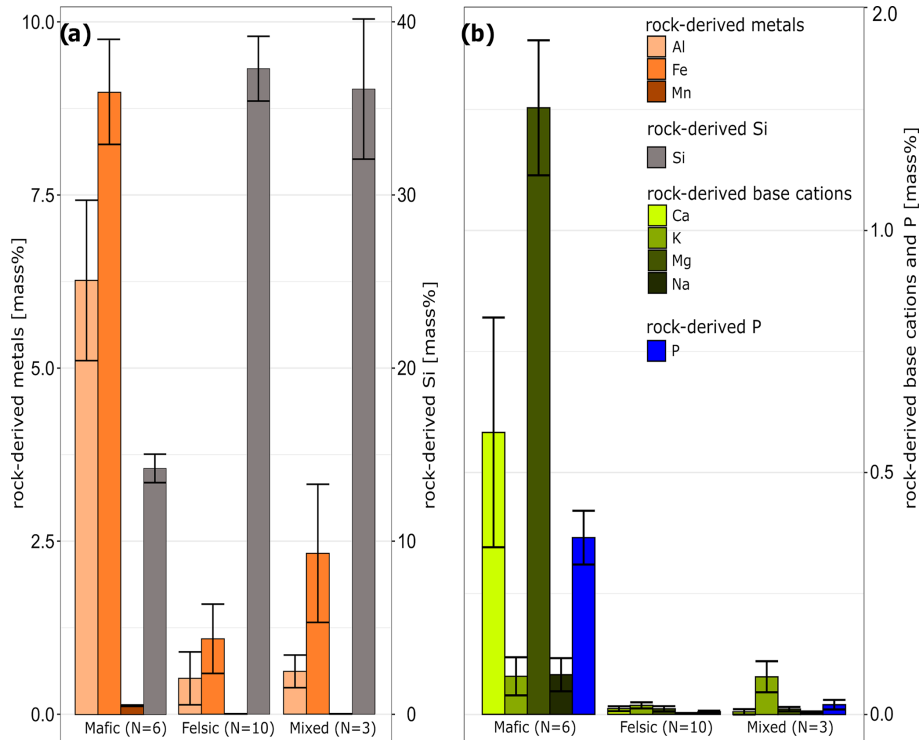

All collected composite samples were kept cooled until being brought to the laboratory (usually within 48 h). In the laboratory, samples were oven-dried at 40 °C for 48–96 h and then weighed (accuracy: ±0.01 g). Derived soil parameters are detailed in Sect. 2.7.

### 2.4.3 Forest inventory and aboveground standing biomass

In 2018, full inventories of the forest tree species and standing aboveground biomass (AGB) were conducted on all forest plots. The forest inventory followed an international, standardized protocol for tropical regions (Matthews et al., 2012). First, we identified, to species level, all living trees with a diameter at breast height (DBH; measured at 1.3 m above ground) greater than 10 cm in each plot. Second, these identified trees were classified into the following empirical DBH classes: 10–20, 20–30, 30–50, and > 50 cm. Third, to estimate the AGB, we constructed stand-specific height diameter ( $H-D$ ) allometric relationships using a representative subset of the plot-specific trees (Méchain et al., 2017). For this, 20 % of all measured, specific trees were selected for height measurement across the DBH range that was recorded per plot. Depending on the tree abundance of each DBH class, the heights of three to five individual trees were then measured using a hypsometer (Nikon Forestry Pro II laser rangefinder, Nikon, Japan). AGB for each individual tree was then estimated using the allometric equation as described by Chave et al. (2014) for moist tropical forests. To estimate wood density data, we used species averages from the DRYAD global wood density database (Zanne et al., 2009). To extrapolate this information for the entire plot for all our sites, we applied a stand-specific height–diameter regression model, modelIH, available within the R package BIOMASS (Méchain et al., 2017). Finally, aboveground standing biomass carbon stock was estimated assuming that all samples standing biomass has a 50 wt % share of C (Chave et al., 2005). A re-census was carried out in 2020, in order to detect changes in aboveground standing biomass and to determine tree mortality. Tree mortality rate ( $\lambda$ ) at each plot was assessed following Lewis et al. (2004) using inventories conducted in 2018 and 2020. The tree mortality rate was calculated for all tree stems with DBH > 10 cm in every plot.

### 2.4.4 Canopy leaves

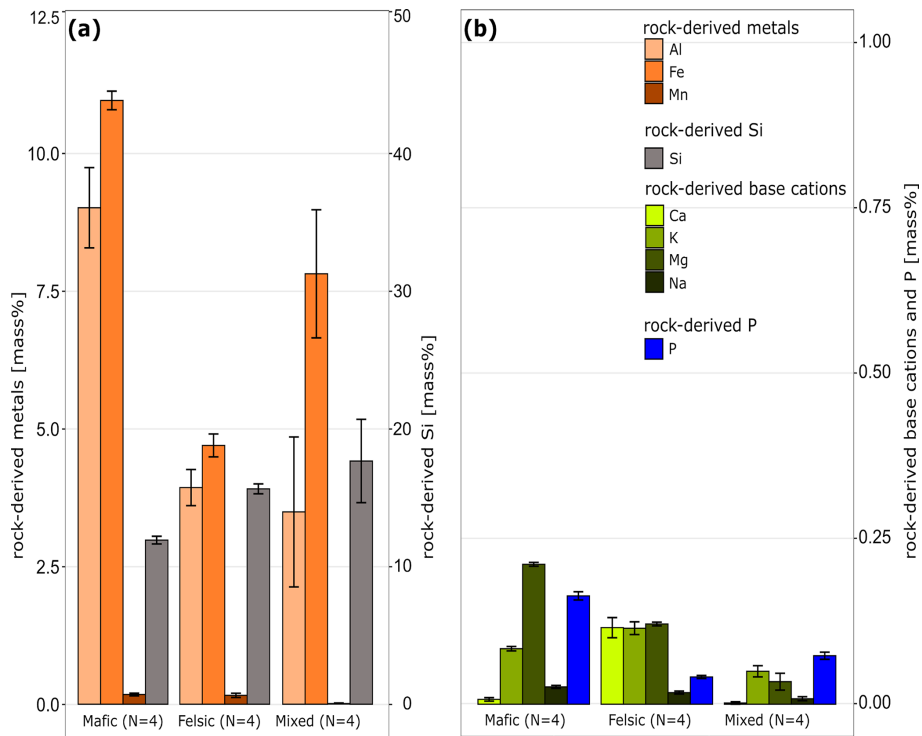

To assess plant functional traits (leaf nitrogen, phosphorus, potassium, magnesium, and calcium content) of living canopy leaves (see Sect. 2.7), we sampled, at the beginning of the weak dry season (December–February), sun-exposed shoots from the outer canopy of selected tree species that collectively make up 80 % of the standing basal area per plot

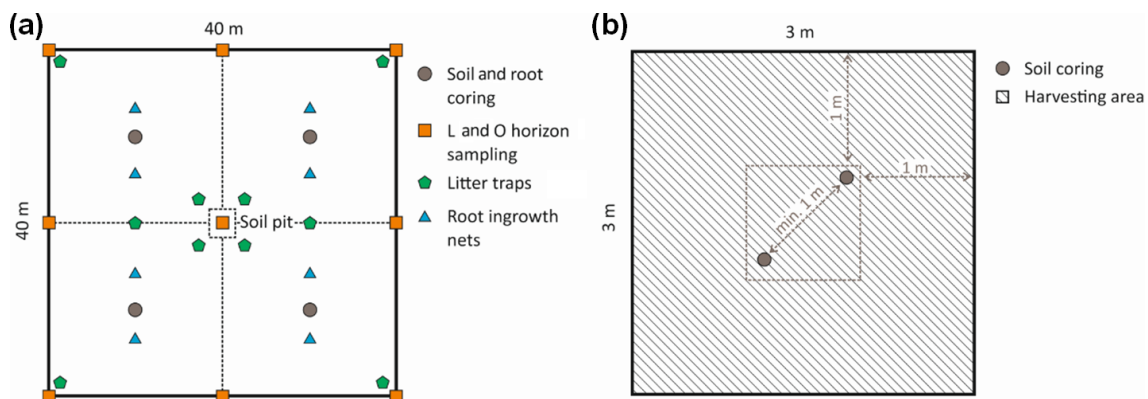

**Figure 3.** Chemical composition of unweathered rock samples representing the parent material for soil formation in three studied geochemical regions (mean  $\pm$  standard error). Panel (a) shows the distribution and concentration of rock-derived aluminum (Al), iron (Fe), and manganese (Mn) and total silica content (Si). Panel (b) shows the distribution and concentration of rock-derived calcium (Ca), potassium (K), magnesium (Mg), sodium (Na), and phosphorus (P). Note the difference in scale on the y axis between panels (a) and (b).

**Table 1.** Topographic information of TropSOC plots across different geochemical regions and land use. Slope and altitude are displayed as minimum and maximum values. Each topographic position per geochemical region contains the range between three and seven field replicate plots.

Felsic region (Uganda)						
Topographic position	Forest plots			Cropland plots		
	Plateau	Sloping	Valley	Plateau	Sloping	Valley
Slope (%)	3–5	9–55	3	1–5	7–50	1–5
Altitude (m) a.s.l	1304–1306	1271–1420	1272–1277	1507–1797	1466–1830	1587–1768
Mafic region (DRC)						
Topographic position	Forest plots			Cropland plots		
	Plateau	Sloping	Valley	Plateau	Sloping	Valley
Slope (%)	3	11–60	1–2	0–5	8–43	0–3
Altitude (m) a.s.l	2208–2227	2188–2248	2181–2310	1477–1731	1486–1774	1505–1708
Mixed sedimentary region (Rwanda)						
Topographic position	Forest plots			Cropland plots		
	Plateau	Sloping	Valley	Plateau	Sloping	Valley
Slope (%)	3	9–60	1	3–5	8–50	2–5
Altitude (m) a.s.l	1908–1939	1891–2395	1882–1889	1719–1837	1565–1952	1556–1758

**Figure 4.** Soil chemical composition of subsoil in stable, old-growth closed-canopy forests (no erosion) in the three investigated geochemical regions (mean  $\pm$  standard error). The data illustrate the convergence of elemental concentrations between the three regions as a result of weathering and soil development. Abbreviations explained in Fig. 3. Note the difference in scale on the y axis between panels (a) and (b).

**Figure 5.** Overview of forest (a) and cropland (b) plot sampling design. Forest plots were subdivided into four 20 m  $\times$  20 m subplots, and one soil profile pit was established per topographic position in each geochemical region for one of three replicate plots.

with the help of trained tree climbers and following a sampling protocol described in Pérez-Harguindeguy et al. (2016). For every tree species, we selected at least 3 individual trees, and a minimum of 5 and maximum of 17 trees per plot were sampled for mature, healthy-looking (= without signs of herbivory) individual canopy leaves. Where sampling of outer canopy leaves was physically not feasible, partially shaded leaves situated below the uppermost canopy were sampled.

## 2.5 Sampling design cropland

### 2.5.1 Cropland plot installation

Plots on cropland were established following a stratified random approach using the same slope classification and selection criteria as for forest sites. However, cropland plots belonging to the same geochemical region and topographic position were not connected along a hillslope catena. On cropland, only fields that were currently covered by cassava were sampled. Cassava fields were chosen since cassava is one of

the most important food crops in the region and is harvested for both tubers and leaves. Rotations of cassava, maize, pulses, and vegetables are common throughout the area, and two harvests are possible per year. The main varieties of cassava on our sites were Mwabailon, Nabiombo, Mwamizinzi, Sawasawa (in eastern DRC), Bukalasa, Shayidire, Gitamisi, Amaduda (in Rwanda), Sambati, and Mubalaya (in Uganda). Only fields without soil protection measurements (i.e., terraced systems) were sampled. For an overview of forest plot sampling design, see Fig. 5b.

### 2.5.2 Soil sampling

Soil sampling was carried out in the same way as for forest soils with the exception that only two cores were combined per plot taken within a 3 m × 3 m area to create depth-explicit composite samples. A total of 100 cropland plots were sampled this way (Fig. 5) with 3–7 field replicate plots per topographic position (plateaus, slopes, valleys) in each geochemical region. No organic litter layers (L and O horizons) were present in cropland, and no soil profile description was carried out. Derived soil parameters are detailed in Sect. 2.7.

### 2.5.3 Biomass and crop yield

As part of the regional stratified random sampling design for cropland plots (see cropland plot installation), biomass from different cassava varieties was collected for 65 plots out of the 100 sampled cropland plots. Biomass was sampled shortly before harvest, approximately at the time of the plant tuber's maximum development. The timing of harvest differed between 12 and 24 months after planting depending on the variety and season. Within each plot, a 3 m × 3 m sampling area was chosen close to the center of each field, and all cassava plants in this area were counted and harvested. The biomass of all plants was separated into leaves, stems, and tubers. These parts were then weighed separately and individually at the time of sampling (i.e., in a field moist state).

### 2.5.4 Land use history and management assessment

Farmers were sent a questionnaire to collect information on the land use and management history of sampled fields following McCarthy et al. (2018). This questionnaire was completed for a corresponding total count of 87 out of the 100 sampled cropland plots.

## 2.6 Monitoring design

### 2.6.1 Micrometeorological data

Three weather stations (ATMOS 41, Meter, Germany) were installed in August 2018, one in each geochemical region of project TropSOC close to the investigated forest catenae (mafic: latitude  $-2.324457^\circ$ , longitude  $28.740818^\circ$ ; felsic: latitude  $0.561767^\circ$ , longitude  $30.356808^\circ$ , mixed sedi-

mentary rocks: latitude  $-2.460503^\circ$ , longitude  $29.095251^\circ$ ). An additional weather station was installed in the mafic region near a cropland catchment (latitude  $-2.583984^\circ$ , longitude  $28.715298^\circ$ ) which was selected for high-resolution erosion monitoring (see Wilken et al., 2021). Furthermore, a meteorological station in the city of Bukavu (latitude  $-2.499979^\circ$ , longitude  $28.845009^\circ$ ) and one in Lukananda (latitude  $-2.344073^\circ$ , longitude  $28.750937^\circ$ ) were put into operation. All stations collected data at a temporal resolution of 5 min on precipitation, air temperature, relative humidity, and air pressure. Additionally, global radiation and wind speed were measured at the Bukavu and Lukananda stations.

### 2.6.2 Litterfall sampling

Litterfall was assessed following a standardized protocol to measure tropical forest carbon allocation and cycling (Matthews et al., 2012). At each of our 36 forest soil sampled plots, 10 litter traps were installed and distributed evenly and systematically per plot. These had a diameter of 60 cm each and were installed at a height of 1.0 m above ground. Litter samples were collected every two weeks for the period between August 2018 and February 2020 and later aggregated to assess seasonal and annual variability in litter productivity and quality (see Sect. 2.4). Collected litter included all organic residues collected by the traps. Larger dead animals and woody material > 2 cm in diameter were discarded. After sampling, material from all 10 traps per plot was mixed to obtain a composite sample. These composite samples were taken to the laboratory the day of sampling, oven-dried at  $70^\circ\text{C}$  for 72 h, and subsequently weighed (dry weight, accuracy:  $\pm 0.01$  g). Data are provided as megagrams per hectare per day ( $\text{Mg ha}^{-1} \text{d}^{-1}$ ) per plot and as the sum of total litter production per plot, aggregated at the seasonal and annual level. The considered seasons were categorized based on the average precipitation for each period: weak dry season (December–February), strong wet season (March–May), strong dry season (June–August), and weak wet season (September–November).

### 2.6.3 Belowground standing root biomass

For all soil-sampled forest plots, standing root biomass and fine root production were assessed from September 2018 to December 2019. Sampling took place once per season within this period (one coring every 3 months), and a total of three rainy seasons and three dry seasons in 2018 and 2019 were covered. Each plot was divided into four equally sized subplots of 20 m × 20 m. Prior to deciding the root sampling strategy and size of depth intervals, root distribution was assessed using soil profiles that were dug in the plot centers for soil classification purposes. This assessment revealed that roots mostly dominated the organic horizons and the upper 50 cm of mineral soil (data not shown).

Belowground standing root biomass was sampled using a soil core sampler (Vienna Scientific Instruments, Austria). Two cores were sampled per subplot in which undisturbed soil cores were divided into five depth layers: one organic soil layer (O horizon), and four mineral soil layers from 0–10, 10–20, 20–30, and 30–50 cm. After transport to the laboratory, each sample was rinsed inside a 2 mm sieve; roots were separated into fine roots ( $\leq 2$  mm diameter) and coarse roots ( $> 2$  mm diameter) using calipers. In addition, fine and coarse roots were separated into living and dead roots based on criteria such as color, root elasticity, and the degree of cohesion of cortex, periderm, and stele; i.a. roots were considered living when root steles were bright and resilient (Osttonen et al., 2005). The dry mass of isolated roots per plot was assessed after previously having dried the root samples at 70 °C for 72 h. Data are provided as milligrams per cubic centimeter ( $\text{mg cm}^{-3}$ ) per plot per sampling date and are also aggregated at the seasonal and annual level.

#### 2.6.4 Fine root net primary production

Fine root net primary productivity was assessed using the ingrowth net method following Ohashi et al. (2016). Two net sheets (polyester mesh aperture size 2 mm, 10 cm wide, 20 cm high) were installed per subplot in a regular pattern with a distance of approximately 1 m between the two nets. Each net was vertically inserted in the top 20 cm of soil starting from the surface of the mineral layer. Nets were sampled every 3 months after installation and seasonally four times a year from September 2018 to December 2019. Data are provided as grams per square meter ( $\text{g m}^{-2}$ ) and grams per square meter per day ( $\text{g m}^{-2} \text{d}^{-1}$ ) of total fine root production per plot over a certain period of time, and they are also provided aggregated at the seasonal and annual level.

#### 2.7 Chemical and physical analyses

A wide range of chemical and physical parameters were assessed for the sampled soil and plant material with the aim to characterize (i) indicators of soil redistribution, (ii) the degree of soil weathering, and (iii) the physical structure of soil, as well as (iv) soil fertility and (v) soil organic carbon characteristics, in order to link them to (vi) functional traits of the sampled biomass, (vii) biomass production, and (viii) land management. For a full overview of all assessed parameters including their assessment methods, please consult the meta-data accompanying the database.

Among others, key measured parameters encompass the following:

##### *Basic physical parameters*

- Soil bulk density
- Soil texture
- Soil water holding capacity

##### *Basic chemical parameters*

- Soil pH (KCl)
- Soil potential cation exchange capacity and its base saturation
- Soil effective cation exchange capacity and its base saturation
- Main elemental composition of bulk soil (Al, Fe, Mn, Si, Ti, Zr, P) and the total reserve in base cations (Ca, Mg, Na, K) in rock parent material, soil, litter, and vegetation samples
- Pedogenic oxide concentration (Al, Fe, Mn)

##### *Available nutrients*

- Dissolvable soil organic nitrogen and carbon
- Plant available phosphorus in soil

##### *Organic matter characteristics*

- Total and organic carbon and nitrogen content in rock parent material, soil, litter, and vegetation samples
- Bulk soil radiocarbon signature
- C : N ratio in soil, litter, and vegetation samples
- Soil carbon stabilization mechanisms

##### *Microbial activity*

- Heterotrophic soil respiration (including isotopic signature of respired gas)
- Microbial biomass during incubation
- Extracellular enzyme activity during incubation

##### *Soil redistribution*

- 239 + 240 Pu activity

All of the parameters listed above have been measured in soil for three depth layers (0–10, 30–40, 60–70 cm) representing distinct sections of the soil profile. Physico-chemical key properties of the remainder of the soil samples in other soil layers have been assessed using mid-infrared spectroscopy and predicted following the workflow of Summerauer et al., (2021). An overview of chemical and physical key soil parameters is provided in Appendix Table A1. Note that all physico-chemical soil properties and the corresponding mid-infrared data are part of the central African spectral library (Summerauer et al., 2021), which minimizes the need for future traditional soil analyses.

## 2.8 Milestones reached

Overall a total of approximately 2100 soil and rock samples were collected, of which about 10%–30% were used for yet more detailed analyses in different experiments by our group (see below). Additionally, 6000 above- and below-ground biomass and litter samples were taken during several sampling and monitoring campaigns at forest and cropland sites. Several thousand near-infrared and mid-infrared (NIR-MIR) spectra in the wavenumber range 600 to 7500 cm<sup>-1</sup> (wavelength 1333.7–16666.7 nm) were collected across the sampled plant and soil samples and were used to train calibration models for each property to predict spatially and depth-explicit soil parameters in relation to soil fertility, carbon stocks, and carbon stabilization using partial least square regressions following the workflow of Summerauer et al. (2021). Furthermore, since 2018, continuous monitoring has been carried out for the installed weather stations, and vegetation dynamics in tropical forests have been assessed from August 2018 until December 2019. Water and heat fluxes between soil and atmosphere are monitored using several weather stations and soil probes.

Analyses conducted on collected samples so far contributed to scientific advances realized through

- the creation of a data frame of reference samples for calibration used in the newly developed soil spectral library for central Africa (Summerauer et al., 2021)
- an investigation of the role of geochemistry and geomorphic position for soil organic matter stabilization mechanisms and patterns of soil organic carbon (SOC) stocks in tropical rainforests (Reichenbach et al., 2021)
- an investigation of the role of geochemistry and geomorphic position on the heterotrophic soil respiration (Bukombe et al., 2021)
- an assessment of the suitability and the application of radioisotope <sup>239+240</sup>Pu inventories for studying soil erosion processes in tropical forests and cropland (Wilken et al., 2021)
- soil fractionation and incubation experiments encompassing cropland soils along geomorphic and geochemical gradients (unpublished).

As part of this paper, the entirety of TropSOC's data is available as an open-access database with extensive metadata documenting experimental approaches, framing of the analyses, data quality, and methodology. An overview of all datasets presented in this database is given in Appendix Table A2.

In summary, TropSOC's first results demonstrate that even in deeply weathered tropical soils, parent material has a long-lasting effect on soil chemistry that can influence and control microbial activity, the size of subsoil C stocks, and the

turnover of C in soil. Soil parent material and the resulting soil chemistry need to be taken into account in understanding and predicting C stabilization and turnover in tropical forest soils. Given the investigated rates of erosion on cropland, our findings confirm the threat of large losses of organic matter leading to a sharp decline in soil fertility with little potential for soils to recover from nutrient losses naturally on decadal or centennial timescales. TropSOC highlights that considering feedbacks between geochemistry and topography to understand the development of soil fertility in the African Great Lakes regions can significantly improve our insights into the role of tropical soils to reach several key sustainable development goals, such as climate mitigation, zero hunger, and to help raise awareness of the need to maintain sufficient soil resources for future generations. Future work realized in project TropSOC based on the database will provide further insights into biomass and plant trait responses to soil geochemistry in forests, as well as cassava yield responses and SOC dynamics in cropland along the investigated geomorphic and geochemical gradients across the region.

## 3 Structure of TropSOC project database (TropSOC v1.0)

### 3.1 Database hierarchy

Datasets are given as tab-delimited .csv files. For each .csv file the metadata describing data structure and assessment methods are given in a .pdf file of the same name. Moreover, additional .pdf files for each main section of the database (basic information, forest, cropland, and microscale meteorology) are given, providing an overview of the structure within each section. Note that the “basic information” section of the database provides the linkages between individual data points, e.g., from soil analysis and the location and/or soil depths where these samples were acquired (for linkages, see also Fig. 6).

### 3.2 Database infrastructure

#### 3.2.1 Basic information

The database comprises basic information of all plots and single point sampling positions where data were collected during project TropSOC. An overview of the structure of the database is presented in Appendix Table A2. The basic information of the database is structured in the following way.

*Part 1.* This is the location and basic background information for all plots and points where data were collected. Data can be found in file *11\_plots\_points.csv*, with descriptions given in *11\_plots\_points.pdf*.

*Part 2.* This includes the sample identifier for the database's internal connection between location of plots, points, and soil data from different soils depths, as well as vegetation data. Data are stored in *12\_sample\_identifier.csv*, with descriptions given in *12\_sample\_identifier.pdf*.

**Figure 6.** Overview of linkages between datasets in the TropSOC database v1.0. Note that for each data .csv file a .pdf file is given detailing the metadata of the respective data sheet.

The key element to link all data tables for which data were collected and analyzed is the plot ID and its derivative, the sample ID. This identifier allows us to link the results from sample analysis with the locations given in *11\_plots\_points.csv*. This results in a n:1 connection between *12\_sample\_identifier.csv* and *11\_plots\_points.csv*. See metadata file *11\_plots\_points.pdf* for an overview of the structure of the plots ID and *12\_sample\_identifier.pdf* for an overview of the structure of the sample ID.

### 3.2.2 Forest

TropSOC's forest data consist of seven parts (Table A2 for overview) structured as paired .csv-.pdf files containing the data (.csv) and accompanying metadata (.pdf) describing parameters and methods. Additionally, an overview of all collected forest data is given in file *2\_forest.pdf*.

*Part 1.* Above- and belowground vegetation data were acquired in 2018, 2019, and 2020 at all forest plots, comprising 13 datasets (dataset files 2.1.1–2.1.13).

*Part 2.* Mineral soil layer data were acquired in 2018 at all forest plots, comprising three data sets (dataset files 2.2.1–2.2.3).

*Part 3.* Organic soil layer data were acquired in 2018 at all forest plots, comprising one dataset (dataset file 2.3).

*Part 4.* The  $^{239+240}\text{Pu}$  soil inventory was carried out in 2018. In contrast to parts 1 to 3 of the forest data, Pu data represent individual points and do not follow the plot concept in a strict manner (dataset file 2.4).

*Part 5.* Soil experiments were carried out from 2018 to 2020, comprising three datasets with results from laboratory soil incubation and fractionation experiments and additional data from soil sample analyses (dataset files 2.5.1–2.5.3).

*Part 6.* Parent material elemental composition was analyzed based on unweathered rock samples taken within plots or from nearby road cuts and mines surrounding the study sites (dataset file 2.6).

*Part 7.* Soil profile descriptions were done in soil pits at the center of plots following WRB-FAO soil description (dataset file 2.7).

### 3.2.3 Cropland

TropSOC's cropland data consist of the following seven parts (Table A2 for overview), structured as paired .csv-.pdf files containing the data (.csv) and accompanying metadata (.pdf) describing parameters and methods. Additionally, an overview of all collected cropland data is given in file *3\_cropland.pdf*.

*Part 1.* Biomass and management data were acquired in 65 and 87 out of 100 sampled cropland plots respectively, comprising two datasets (dataset files 3.1.1–3.1.2).

*Part 2.* Data on mineral soil layers were acquired in 2018 for 100 cropland plots and comprising three datasets (dataset files 3.2.1–3.2.3).

*Part 3.* Pu soil inventory was carried out in 2018. In contrast to parts 1 and 2 of the cropland data, Pu data represent individual points and not plots and were sampled across several catchments (dataset file 3.3).

*Part 4.* For soil experiments, this part of the database comprises two datasets with results from laboratory soil incubation and fractionation experiments and additional data from soil sample analyses (dataset files 3.4.1–3.4.2).

### 3.2.4 Meteorological data

The meteorological data comprises four parts (Table A2 for overview), structured as paired .csv-.pdf files containing the data (.csv) and accompanying metadata (.pdf) describing parameters and methods.

*Part 1: locations of meteorological stations.* This includes coordinates, elevations, and contact addresses for the respective data (dataset file 4.1).

*Part 2: daily meteorological data.* Six meteorological stations recorded precipitation, air temperature, relative humid-

ity, air pressure, solar radiation, and wind speed (dataset file 4.2).

*Part 3: high-resolution 5 min triggered precipitation data.* Precipitation was recorded at the time of tipping bucket tilt at a resolution of 5 min (dataset file 4.3).

## 4 Database status

### 4.1 TropSOC v1.0

The current version, v1.0, of TropSOC includes several thousand individual plant and soil samples collected across 136 sites, spanning cropland and forests in the East African Rift Valley system and a large variety of parameters. A total of 36 .csv data sheets are available that give all analyses completed for specific samples. Data sheets are structured according to the descriptions given in Sect. 3 and described and elaborated on in the accompanying metadata files. The current distribution of data points across the various levels of the database hierarchy is shown in Table 2. All individual data entries present in the database have passed quality control completed by experts who were involved in the creation of the data. When applicable, reports on the quality assessment of each parameter can be found in the metadata .pdf files accompanying the .csv files.

### 4.2 Accessing TropSOC v1.0, asking questions, and reporting issues to its hosting platform CBO

Users may access the TropSOC database v1.0 and its supporting information through the Supplement provided as part of this submission. Version 1.0 of the database is also available through the data download section of the Congo Biogeochemistry Observatory (CBO) (<https://www.congo-biogeochem.com/data>, last access: 10 August 2021) and the PANGEA open-access environmental data repository. CBO is a consortium of multinational researchers from Africa, Europe, and the United States who study biogeochemical cycles and atmosphere–plant–soil interactions in tropical Africa with a focus on the Congo Basin and the African Great Lakes region (Doetterl et al., 2020). The dedication of young African researchers to understand and preserve the threatened natural resources of their home countries is paired with the resources of some of the most experienced and largest research groups focusing on African tropical forest and agroecosystems. Founded in 2018 by scientists of several African and European institutions and supported by multinational organization such as the Consultative Group for International Agricultural Research's International Institute of Tropical Agriculture (CGIAR-IITA) and the World Agroforestry Centre (CGIAR-ICRAF), CBO has become an important scientific network in tropical Africa for studying biogeochemistry in soils and sediments, creating synergies between key local institutions and international researchers which are crucial for the implementation

**Table 2.** Overview of the current number of data points in TropSOC v1.0 on plant, soil, and meteorology and their affiliation to the hierarchical levels of forest and cropland. Numbers in tables refer to the number of data entries at the lowest available aggregation level (= highest resolution of data). For details on parameters, see the corresponding metadata descriptions. Note that collected weather station data in the felsic (Uganda) and mixed sediment region (Rwanda) represent both cropland and forest, while separate stations were available for the two land cover classes in the mafic region (DRC). Abbreviations: SOM = soil organic matter.

Plant–soil observations	Plots	Bulk soil samples (0–100 cm soil depth, 10 cm increments)	Bulk vegetation samples (above/ belowground)	Incubated soil layers	SOM fractionated soil layers	Plots with vegetation assessments
Forest	36	916	1437/4374	112	145	40
Cropland	100	1190	132/66	131	159	65
Total	136	2106	1569/4400	243	304	105
Meteorological observations	Stations	Precipitation	Air temperature	Relative humidity	Global radiation	Wind speed
Felsic region	1	541	541	541	0	0
Mafic region (forest)	1	674	858	860	860	644
Mafic region (cropland)	3	1310	1310	1312	709	650
Mixed sediment region	1	90	520	565	0	0
Total	6	2615	3229	3278	1569	1294

of research in remote and difficult to access environments. Research at CBO is funded and supported by German, Belgian, US, and Swiss research foundations and linked to research institutes at Ghent University, Augsburg University, Florida State University, ETH Zurich, the University of Louvain, TU Dresden, and the Max Planck Society.

Users are encouraged to provide feedback and corrections to existing data if problems are discovered by contacting CBO (contact@congo-biogeochem.com) or the corresponding author of this paper (sdoetterl@usys.ethz.ch). Corrections will be implemented in consecutive versions of the database that can be downloaded via the CBO site.

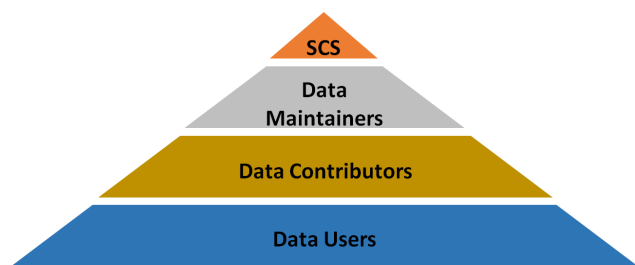

#### 4.3 Consecutive database versioning and archiving

Updated versions of the database will be periodically released following either substantial changes or new peer-reviewed publications using the dataset. The versions of these official releases are tracked using an associated version number, e.g., TropSOC v1.0, and so on. These official releases will be archived at ETH Zurich's Research Collection via ETH's Soil Resources Group (<https://soilres.ethz.ch/>, last access: 10 August 2021) and CBO's data storage (<https://www.congo-biogeochem.com/data>, last access: 10 August 2021) with a dataset DOI issued for each release via ETH Zurich so that users may revert back to the earlier version if so required. These archived releases will be maintained in perpetuity to facilitate reproduction of any analyses conducted using a past version of the database. When accessing the dataset and using it for one's own research, users commit to cite the original paper provided here in addition to the version number, DOI, and any description provided to future versions of the database (see Sect. 6 for details).

## 5 Database governance and participation

TropSOC is a community effort with multiple contributors operating at different levels (Fig. 7). Governance of TropSOC is required in order to ensure continuity of services and to plan for the future evolution of this data repository. Studying the rapid environmental changes to the African Tropics is a central research objective for the scientists of the Congo Biogeochemistry Observatory (CBO) making it the ideal body to govern future versions of TropSOC. The governance structure of TropSOC is briefly described in Fig. 7. While the TropSOC core team is responsible for the original version of the database, its maintenance, management, and archiving, scientists involved in the CBO oversee the establishment of cooperative agreements in the long term and act as a steering committee for modifications to TropSOC suggested by the research community. The main role of the steering committee is to determine the feasibility of major changes to TropSOC proposed by the community and to coordinate activities that would build upon TropSOC or continue similar research work within the framework of CBO. Although the structure of TropSOC is oriented around individual and research projects, the nature of scientific research is often more group-focused. For example, teams of researchers generally work together to seek out funding and to conduct research. Thus, in some cases a group or team of individuals may seek to utilize or modify TropSOC for their purposes. Such groups can petition the scientific steering committee (SCS) to be formally designated a CBO member group. Approved organizations should nominate a member to serve on the steering committee.

Interested researchers are also invited to contribute data to future versions of TropSOC in order to grow the database. Anyone can be a data contributor provided they agree to the

**Figure 7.** A simplified depiction of the TropSOC governance. The scientific steering committee (SCS) is responsible for approving major management decisions. The TropSOC core team as data maintainers are responsible for implementing broader changes together with new data contributors. All interested scientists are welcome to contribute data to future versions of the database or access the data for their own research.

terms of use and follow the proper steps for contributing data to TropSOC. If such suggestions arise, the CBO steering committee together with the TropSOC core team are responsible for approving the suggested changes and additions to the database. Upon approval, the TropSOC core team will coordinate with the new data contributors to implement the suggested data additions. In the case of organizations or individuals making larger changes or additions to TropSOC, a designated data maintainer from new contributor groups is required to coordinate the technical aspects of the implementation of changes together with the TropSOC core team. Within the pool of data contributors, individuals with significant experience working with TropSOC may be designated by either the steering committee or database maintainers as expert reviewers. These individuals are tasked to assist maintainers and oversee peer review and quality assessment of contributed new entries.

## 6 Data availability

All data presented in this study is part of the publication and added as a Supplement consisting of data tables (.csv) and accompanying metadata descriptions (.pdf files). In addition, the database and its metadata are archived and published in the open-access environmental and geoscience data repository GFZ Data Services, accessible at <https://doi.org/10.5880/figeo.2021.009> (Doetterl et al., 2021). Additionally, the database is accessible via the website of the Congo Biogeochemistry Repository (<https://www.congo-biogeochem.com/data>, CBO, 2021). Updated versions of the database will be made available as version updates in both repositories. As detailed above, TropSOC is an open-source project that provides several ways for participation. Anyone may share the TropSOC dataset provided in accordance with the Creative Commons Attribution 4.0 International License (CC BY 4.0) and by citing the correspond-

ing references of the original database description and future modifications under their separate DOI.

## 7 Conclusions and outreach

The TropSOC database is an attempt to gather the data used in individual studies in one place and in the same format to facilitate comparisons and synthesis activities. TropSOC is unique in that it includes measurements and monitoring data of bulk soil and vegetation responses in the African tropical context on carefully selected and comparable land use, geomorphic, and geochemical gradients on the landscape scale. Building on the data gathered along these gradients during several years of field activities and carrying out numerous lab experiments to investigate the impact of soil geochemistry and land degradation on biogeochemical cycles in tropical plant–soil systems, TropSOC is, to the best of our knowledge, the largest integrative project database on plant–microbial–soil systems in the Congo Basin to date. TropSOC’s open-access database structure and participatory approach makes it a suitable tool for scientists to study experimentally defined soil disturbance and plant responses, as well as to test some of the assumptions behind modeling biogeochemical cycles in land surface models. Furthermore, we hope to encourage the community to increase the effectiveness of that investment and to use the TropSOC database as a repository to increase the impact of their own research results. As such, TropSOC is an interactive database that is open for contributions. In addition, TropSOC now manages one of the largest topically structured soil and plant sample archives for tropical eastern Africa with several thousand samples and more than three tons of plant and soil material stored at ETH Zurich. Subsamples of all the above are available upon request to interested researchers.

Finally, we hope that work based on the TropSOC database can help to provide answers on the role and magnitude of geochemistry, as well as soil mobilization, in controlling biological processes and fluxes of carbon and nutrients in the tropics in order to better constrain soil processes in models ranging from profile to global scales (Todd-Brown et al., 2013). Reducing the uncertainties associated with our understanding of tropical (agro-)ecosystems in diverse but rapidly changing landscapes is one of the most pressing issues for securing the future well-being of hundreds of millions of people and to constrain land loss in an area that is home to some of the last and most fragile populations of great apes in the wild. Further, elucidating the gravity of the consequences for soil functioning that can be observed in TropSOC’s study area can contribute to reducing the large uncertainty associated with terrestrial biogeochemical processes in models. Finally, our hope is that studies based on TropSOC’s data will also help to raise further awareness for the necessity of creating the socioeconomic fundamentals for sustainable land management in tropical Africa.

## Appendix A

**Table A1.** Basic chemical and physical soil parameters aggregated at land use and geochemical regions. Displayed are average values and standard deviations taken over 10 soil increments at 10 cm from 0–100 cm soil depth derived from NIR-MIR spectral data, calibrated on samples from three depth increments (0–10, 30–40, and 60–70 cm). See metadata files 223\_soil\_spec.pdf and 323\_soil\_spec.pdf for details. Abbreviations: CEC = potential cation exchange capacity; ECEC = effective cation exchange capacity; Si = silica; Al = aluminum; Fe = iron; Mn = manganese; SOC = soil organic carbon; SON = soil organic nitrogen; P = phosphorus; TRB = total reserve in base cations; BD = bulk density. All assessment methods are explained in the corresponding .pdf metadata files accompanying the database.

**Table A2.** Structure of the TropSOC database. For each topic a .pdf file is given that contains an overview of the available data on soil, vegetation, and weather collected for the investigated forest and cropland plots. Each dataset then comprises a data-containing .csv file and an additional metadata-containing .pdf file of the same name.

	Introduction and structure of the database	0_intro_structure.pdf
1	Basic information	1_basic_information.pdf
1.1	Location and basic background information for all plots and points where data were collected	11_plots_points.csv/pdf
1.2	Database internal connection between location of plots and points and soil data from different soil depths	12_sample_identifier.csv/pdf
2	Forest	2_forest.pdf
2.1	Vegetation	
2.1.1	Forest inventory	211_forest_invent.csv/pdf
2.1.2	Forest inventory aggregated	212_forest_invent_agg.csv/pdf
2.1.3	Fresh leaves chemistry	213_fresh_leaves.csv/pdf
2.1.4	Fresh leaves chemistry aggregated at species level	214_fresh_leaves_agg.csv/pdf
2.1.5	Litter fall	215_litter.csv/pdf
2.1.6	Litter fall aggregated to seasonal values	216_litter_seasonal.csv/pdf
2.1.7	Litter fall aggregated to annual values	217_litter_annual.csv/pdf
2.1.8	Root biomass	218_root_biomass.csv/pdf
2.1.9	Root biomass aggregated to seasonal values	219_root_biomass_seasonal.csv/pdf
2.1.10	Root biomass aggregated to annual values	2110_root_biomass_annual.csv/pdf
2.1.11	Root productivity	2111_root_prod.csv/pdf
2.1.12	Root productivity aggregated to seasonal values	2112_root_prod_seasonal.csv/pdf
2.1.13	Root productivity aggregated to annual values	2113_root_prod_annual.csv/pdf
2.2	Mineral soil layers	
2.2.1	Soil carbon and nitrogen including organic matter fractions	221_soil_carbon.csv/pdf
2.2.2	Physicochemical soil properties from laboratory analyses	222_soil_phy_chem.csv/pdf
2.2.3	Physicochemical soil properties from NIR-MIR spectroscopy	223_soil_spec.csv/pdf
2.3	Organic soil layers	231_soil_organic_layer.csv/pdf
2.4	Pu soil inventory	241_pu_inventory.csv/pdf
2.5	Soil experiments	
2.5.1	Incubation experiments	251_incubation.csv/pdf
2.5.2	Microbial biomass and enzyme experiments	252_microbiology.csv/pdf
2.5.3	$^{14}\text{C}$ data from bulk soil and $\text{CO}_2$ measurements	253_c14.csv/pdf
2.6	Parent material	261_rocks.csv/pdf
2.7	Soil profile descriptions	271_profiles.csv/pdf
3	Cropland	3_cropland.pdf
3.1	Biomass and management	
3.1.1	Biomass yield based on plot data	311_biomass.csv/pdf
3.1.2	Land management data	312_management.csv/pdf
3.2	Mineral soil layers	
3.2.1	Soil carbon and nitrogen including organic matter fractions	321_soil_carbon.csv/pdf
3.2.2	Physicochemical soil properties from laboratory methods	322_soil_phy_chem.csv/pdf
3.2.3	Physicochemical soil properties from NIR-MIR spectroscopy	323_soil_spec.csv/pdf
3.3	$^{239+240}\text{Pu}$ soil inventory	331_pu_inventory.csv/pdf
3.4	Soil experiments	
3.4.1	Incubation experiments	341_incubation.csv/pdf
3.4.2	$^{14}\text{C}$ data from bulk soil and $\text{CO}_2$ measurements	342_c14.csv/pdf
4	Meteorological data	4_meteo.pdf
4.1	Locations of meteorological stations	410_meteo_locations.csv/pdf
4.2	Daily meteorological data from six meteorological stations	420_meteo_daily.csv/pdf
4.3	High resolution 5 min triggered precipitation data	430_meteo_pcp_tig.csv/pdf

**Sample availability.** Remaining soil and plant samples are logged and barcoded at the Department of Environmental Science at ETH Zurich, Switzerland. As long as idle sample mass remains available, samples for independent research and to stimulate collaboration with the CBO network and the TropSOC project group are available upon request. The authors cannot guarantee that they can revisit the study sites in order to provide additional sample material in future campaigns. Samples will be given to researchers free of charge. Sample preparation and transport are subject to a handling fee.

**Supplement.** The supplement related to this article is available online at: <https://doi.org/10.5194/essd-13-4133-2021-supplement>.

**Author contributions.** SD functioned as the project leader. SD and PF were lead coordinators for compiling the database, were responsible for data analysis, and designed the metadata. BB, MC, LK, DM, MR, LS, and FW collected and created datasets and also analyzed these data before their inclusion into the database. RKA, FB, MC, CB, AM, MM, JM, SMM, LN, AS, RU, and CV were technical contributors and participated via data collection. GB, MB, PB, GC, LNC, AH, KK, BBM, BR, JS, BV, KVO, and KV were conceptual contributors and participated in the design of the study, as well as by giving advice and feedback during the campaign. SD and PF wrote the paper. All authors supported data analysis and gave feedback during the writing process.

**Competing interests.** The authors declare that they have no conflict of interest.

**Disclaimer.** Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

**Acknowledgements.** This work is part of the DFG funded Emmy Noether Junior Research Group “Tropical soil organic carbon dynamics along erosional disturbance gradients in relation to soil geochemistry and land use” (TropSOC). Micrometeorological data from three of our weather stations (Bukavu, Lukananda, Bugulumiza) were made available and are administered by the Trans-African Hydro-Meteorological Observatory (TAHMO). The authors would like to thank in particular the following collaborating institutions for the support given to our scientists and this project: International Institute of Tropical Agriculture (CGIAR-IITA), Catholic University of Bukavu (UCB), Mountain of the Moon University (MMU), Kyaninga Forest Foundation (KFF), ETH Zurich, and the Max Planck Institute for Biogeochemistry in Jena. Special thanks goes to the many student assistants for their important work in the laboratory and all guards, sentinels, and field work helpers making the sampling campaign possible under difficult conditions. Lastly, we thank the editors of ESSD as well as the reviewers Yao Zhang and Rose Abramoff for their valuable insights and comments during the review process.

**Financial support.** This research has been supported by the Deutsche Forschungsgemeinschaft (grant no. 387472333).

**Review statement.** This paper was edited by Jocelyn Lavalley and reviewed by Yao Zhang and Rose Abramoff.
