## 39 Abstract

40 The majority of synaptic inputs to the primary visual cortex (V1) are non-feedforward, instead  
41 originating from local and anatomical feedback connections. Animal electrophysiology  
42 experiments show that feedback signals originating from higher visual areas with larger receptive  
43 fields modulate the surround receptive fields of V1 neurons. Theories of cortical processing  
44 propose various roles for feedback and feedforward processing, but systematically investigating  
45 their independent contributions to cortical processing is challenging because feedback and  
46 feedforward processes coexist even in single neurons. Capitalising on the larger receptive fields  
47 of higher visual areas compared to primary visual cortex (V1), we used an occlusion paradigm  
48 that isolates top-down influences from feedforward processing. We utilised functional magnetic  
49 resonance imaging (fMRI) and multi-voxel pattern analysis methods in humans viewing natural  
50 scene images. We parametrically measured how the availability of contextual information  
51 determines the presence of detectable feedback information in non-stimulated V1, and how  
52 feedback information interacts with feedforward processing. We show that increasing the visibility  
53 of the contextual surround increases scene-specific feedback information, and that this contextual  
54 feedback enhances feedforward information. Our findings are in line with theories that cortical  
55 feedback signals transmit internal models of predicted inputs.

56

## Significance Statement

57

65

66

The visual system has circuit mechanisms for processing scene context. These circuits involve lateral and feedback inputs to neurons. These inputs interact with feedforward inputs and modulate neuronal responses to visual stimuli presented outside their receptive fields. Systematically investigating independent contributions of feedback and feedforward processes is challenging because they coexist even in single neurons. Here we use an occlusion paradigm to isolate feedback and lateral signals in human participants viewing natural scene images in fMRI. We show that increasing the visibility of the contextual surround increases scene-specific feedback information, which also enhances feedforward signals. Our findings are in line with theories that cortical feedback signals carry abstract internal models that combine with more detailed representations in primary visual cortex.

81

Sensory stimulation triggers a cascade of processing in a hierarchy of visual areas. This feedforward processing meets recurrent activity from the previous sensory input and triggers recurrent activity that will meet the next expected visual input. Recurrent processing contextualises and predicts the incoming signal and updates internal models and future recurrent streams. The contextualisation of feedforward information by feedback signals is essential for our understanding of cortical processing (Gilbert and Li, 2011). We know from animal recordings that cortical neurons are contextually modulated when their response to a feedforward stimulus feature is modified by the presence of surrounding features (Sugita, 1999; Shushruth, 2011). In visual cortex, this contextual information can be located far in the surround of a neuron's receptive field. Consequently, contextual modulation of neurons is exerted by cortical feedback and lateral inputs (Angelucci, 2002). Cortical feedback inputs, at least in non-human primate cortex, arrive to discrete portions of cortical pyramidal neurons; mainly to the apical dendrites that branch up to layer 1 (Douglas and Martin, 2007). Feedback inputs are therefore

82 computationally distinct from feedforward inputs arriving to basal dendrites. Recent conceptual  
83 shifts in our understanding of neuronal computation are contributing to a developing perspective  
84 on the significance of cortical feedback inputs in determining neuronal information processing  
85 (Larkum, 2013). This perspective requires techniques to probe brain processing that detect  
86 neuronal inputs, advancing previous studies that mainly measure neuronal outputs (i.e. spiking  
87 activity Larkum et al., 2018; Muckli et al., 2015). Functional magnetic resonance imaging (fMRI)  
88 is one such technique that detects pre- and postsynaptic inputs, offering a means to measure  
89 contextual feedback information to a region of cortex.

90         Understanding the nature of contextual modulation transmitted by cortical feedback and  
91 lateral interaction is vital for understanding the brain in behavioural and cognitive contexts  
92 (Gilbert and Sigman, 2007). This importance of cortical feedback and lateral interaction arises  
93 because contextual modulations on a neuron include influences from higher-level top-down  
94 processes including expectation, prior experience and goal-directed behaviour, which originate in  
95 higher cortical areas (Muckli and Petro, 2013). Therefore, describing neuronal substrates of  
96 cognition in brain networks including sensory areas requires us to measure not only stimulus-  
97 driven neuronal responses under discrete states of top-down influences (e.g. attention,  
98 expectation, task, working memory), but also feedback-driven responses in isolation from  
99 feedforward processing. Measuring feedback-driven modulations separate from stimulus-driven  
100 activity allows us to investigate the information contained in top-down influences. These signals  
101 alter neuronal responses to stimuli (Li et al., 2004; Schwiedrzik and Freiwald, 2017; Petro and  
102 Muckli, 2018), which may depend on other state variables (e.g. being conscious, Philips et al.,  
103 2016), therefore functionally determining the brain's response to its environment (Friston, 2010;  
104 Clark, 2015).

105         We used fMRI, a brain imaging measure of energy consumption, and multivoxel pattern  
106 analysis (MVPA) to investigate how global natural scene features contextually modulate human  
107 V1. Our approach complements non-classical receptive field studies in rodent and monkey cortex,  
108 that measure spikes in response to a feedforward stimulus relative to contextual surround

109 stimulation. However, the proposed tuning to pre-and post-synaptic activity in apical dendrites  
110 that might be detectable by fMRI allows us to capitalise on a signal that might not always be  
111 available in sharp electrode electrophysiology, where the input at the apical dendrites might not  
112 lead to a change in spiking output. Using partially occluded images, we parametrically vary the  
113 amount of global contextual information that we provide and measure the resulting contextual  
114 feedback (and lateral interaction) information to V1 both in the absence of feedforward  
115 information, and when feedback is integrated with feedforward information. If global features in  
116 the surround contextually modulate human V1, we hypothesized that scene information in non-  
117 feedforward-stimulated V1 voxels should decrease with progressive masking of the surround, and  
118 increased surround stimulation should modulate detectable scene information even when V1  
119 voxels receive feedforward stimulation.

120

## 121 Materials and Methods

### 122 Subjects

123 We compensated twenty-nine subjects from the University of Glasgow to participate in the  
124 experiment (n = 13 males; mean age: 24.28 years, range: 19-41 years). Subjects provided informed  
125 written consent and the experiment was approved by the local ethics committee at the University  
126 of Glasgow (CSE01063). We excluded subjects if their data was at chance level classification  
127 performance in at least one feedforward control condition (n = 5) or poorly aligned (anatomically)  
128 between functional runs (n = 3, see *Voxel Selection and Analysis*, indicating substantial body  
129 movement between scans). Below we report results from 21 subjects with stable classification in  
130 feedforward control conditions (n = 10 males; mean age: 25.29 years, range 19-41 years).

### 131 Stimuli

#### 132 Feedback vs Feedforward condition

133 We used occluded natural scene stimuli to investigate cortical feedback signals in the  
134 absence of feedforward stimulation (Smith and Muckli, 2010; Muckli et al., 2015; Revina et al.,  
135 2018; Morgan et al., 2019). For the feedback conditions, the lower right image quadrant was

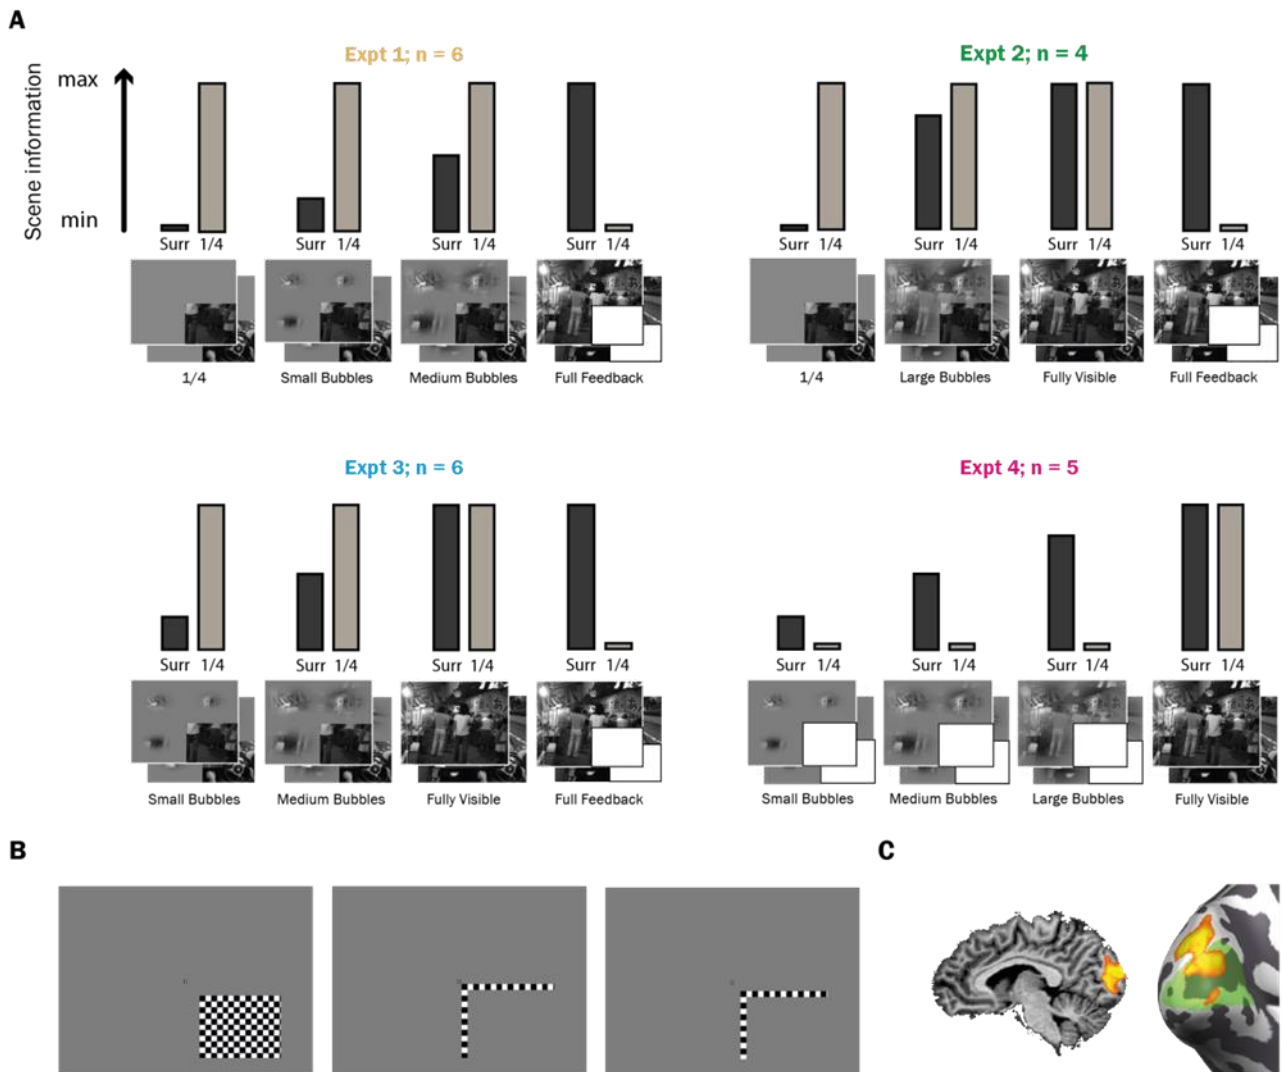

136 occluded by a white rectangle. Here we expect that the retinotopic region of V1 responding to the  
137 white portion of the image receives no meaningful feedforward input and only cortical feedback  
138 signals (and lateral inputs). The white rectangle was placed  $0.5^\circ$  of visual angle diagonally from  
139 the centre of the image and spanned  $11.6^\circ \times 9.2^\circ$ . In the so-called ‘feedforward’ conditions, the  
140 corresponding quadrant of the scene was shown; V1 voxels responding to the lower image  
141 quadrant in this condition contain a mixture of feedforward, lateral and feedback inputs.

## 142 Scenes

143 We used two natural scene images for each participant, as natural scenes induce a lot of  
144 contextual associations (Bar 2004). Each scene was  $600 \times 480$  pixels and spanned  $24^\circ \times 19.2^\circ$  of  
145 visual angle. We did not normalize the images in terms of low-level visual features, such as  
146 luminance, contrast or energy at each spatial frequency because we wanted the scenes to look as  
147 natural as possible. Smith and Muckli (2010) previously showed that contextual feedback signals  
148 in V1 cannot be solely attributed to these low-level visual features.

149 To investigate the contribution of surrounding contextual information on the brain activity  
150 patterns corresponding to the lower right quadrant, we manipulated the visibility of the  
151 surrounding  $\frac{3}{4}$  of the scene with a Gaussian aperture in each quadrant (“bubbles”, Gosselin and  
152 Schyns, 2001) of various sizes to reveal the scene and produce the following types of stimuli:  $\frac{1}{4}$   
153 (no surrounding scene shown), Small Bubbles (standard deviation [SD] =  $50 \times 32$  pixels),  
154 Medium Bubbles (SD =  $90 \times 56$  pixels), Large Bubbles (SD =  $125 \times 100$  pixels) and Full (surround  
155 fully visible). The study consisted of four experiments, with each subject participating in only one  
156 ( $n = 6$ ;  $n = 4$ ;  $n = 6$ ;  $n = 5$  respectively). In each experiment, stimuli were shown in four (out of  
157 the five possible) different conditions (**Figure 1A**). In Experiment 1, we used stimuli in the Full  
158 Feedback occluded condition,  $\frac{1}{4}$  feedforward, Small Bubbles feedforward and Medium Bubbles  
159 feedforward conditions. In Experiment 2, we replaced Small and Medium Bubbles with Large  
160 Bubbles and the Fully Visible scene. In Experiment 3, we added the Fully Visible scene to test  
161 whether more contextual feedback would be seen in the Small and Medium Bubbles conditions if  
162 participants were more familiar with the full scene. In Experiment 4, we tested the effect of

163 reducing the surrounding information around the occluded region using Small, Medium and  
 164 Large Bubbles feedback conditions.

165 **Figure 1.** Stimuli. A) In feedback conditions the lower right image quadrant was occluded with a white rectangle,  
 166 while in feedforward conditions the corresponding quadrant was visible. We manipulated scene visibility around the  
 167 lower right quadrant with bubbles of various sizes to create 5 types of conditions: 1/4, Small Bubbles, Medium Bubbles,  
 168 Large Bubbles and Full. Dark bars labelled “Surr” illustrate the extent to which the surrounding 3/4 of the scene was  
 169 revealed. Light bars labelled “1/4” illustrate the extent to which the lower right image quadrant was revealed. Bars are  
 170 not to scale. B) Checkerboard stimuli were used to retinotopically map the occluded region in V1; left to right Target,  
 171 Near Surround, Inner Border. C) The activation for the contrast of (Target – Near Surround) used to map non-  
 172 stimulated V1 is shown on the occipital cortex on one subject, with V1 in green on the inflated visualization.  
 173

#### 174 Occluded region mapping

175 We presented subjects with three contrast-reversing checkerboards (5 Hz) twice per run.  
 176 The checkerboards either covered an inner rectangular part of the occluded region (*Target* – 2.5°  
 177 diagonally from centre, 10.2° × 7.8° visual angle) or the border between the lower right quadrant  
 178 and the rest of the stimulus (*Surround*). There were two types of surround checkerboard stimuli  
 179 (**Figure 1B**) – *Near Surround* (0.5° diagonally from fixation, 11.6° × 9.2° visual angle) and *Inside*

180 *Border* (1.5° diagonally from fixation). The activation in the early visual areas for the (*Target –*  
181 *Near Surround*) contrast is shown in **Figure 1C**.

## 182 **Experimental Design and Statistical Analysis**

### 183 Task and procedure

184 We presented scenes on a uniform grey background using MRI compatible goggles  
185 (NordicNeuroLab) with 800 × 600 pixel screen resolution, which corresponded to 32° × 24°  
186 visual angle. In each experiment there were 8 types of trial (2 scenes in 4 different conditions). In  
187 each 12 second trial the stimulus was flashed on and off (200 ms on/ 200 ms off) 28 times (11.6  
188 secs + variable fixation to account for uncertainty in timing). This flashing increases the signal to  
189 noise ratio compared to continuous presentation (Kay et al., 2008) and gives rise to a greater  
190 BOLD response (Boynton et al., 1996). Each trial type was presented sequentially, with the trial  
191 order randomized in each sequence. Each sequence lasted 96 seconds (8 × 12 s). A 12 second  
192 fixation period was included before and after each sequence of trials. Each experimental run  
193 lasted 10 min 48 seconds, containing four trial sequences and two mapping sequences (each  
194 mapping sequence consisted of *Target* and two *Surrounds*). There were four experimental runs  
195 in total. Thus, each stimulus was shown 16 times per experiment. Subjects' task was to fixate on a  
196 central checkerboard and report a fixation colour change with a button press. Subjects pressed a  
197 different button depending on whether the colour change occurred during scene 1 or scene 2 (right  
198 index and middle fingers respectively). The purposes of the task were to ensure that the subject  
199 paid attention to which scene was being shown and to minimize eye movements. In addition, we  
200 used eye-tracking to make sure subjects were fixating. Subjects were familiarised with the full  
201 non-occluded scenes in a short practice run prior to going into the scanner. This was done to  
202 increase subjects' contextual associations and thus increase meaningful feedback when viewing  
203 the scenes with reduced information in the experimental trials.

204 After the experimental runs, we performed a polar angle retinotopic mapping procedure to  
205 estimate the borders of the early visual areas V1-3. This consisted of a single checkerboard wedge  
206 which started in the right horizontal meridian and rotated clockwise (12 rotations per scan, wedge

207 angle: 22.5°, scan time: 13 min 28 sec). For 10 subjects, we also performed an eccentricity  
208 mapping procedure. This consisted of an expanding ring which started at the centre and expanded  
209 towards the periphery (8 expansions per scan, ring width increased exponentially towards the  
210 periphery, scan time: 9 min 12 sec).

## 211 MRI acquisition

212 We collected MRI data using a 3T Siemens Tim Trio System with a 12-channel head coil.  
213 We measured blood oxygen level dependent (BOLD) signals with an echo-planar imaging  
214 sequence (echo time: 30 ms, repetition time: 1000 ms, field of view: 210 mm, flip angle: 62°, 18  
215 axial slices). The spatial resolution for functional data was 3 mm<sup>3</sup>. Each experimental run had 648  
216 volumes. Retinotopic mapping consisted of 808 volumes (polar angle) or 552 volumes  
217 (eccentricity). We positioned 18 slices to maximize coverage of occipital cortex. We recorded a  
218 high-resolution 3D anatomical scan (3D Magnetization Prepared Rapid Gradient Echo, 1 mm<sup>3</sup>  
219 resolution, 192 volumes).

## 220 MRI data processing

221 We corrected functional data for each experimental run and retinotopic mapping runs for  
222 slice time (cubic spline interpolation) and 3D motion (Trilinear/Sinc interpolation), temporally  
223 filtered (high-pass filtered at 6 cycles with GLM-Fourier, and linearly detrended), and spatially  
224 normalized data into Talairach space with BrainVoyager QX 2.8 (Brain Innovation, Maastricht,  
225 The Netherlands; Goebel, 2012). We used the anatomical data to create an inflated cortical surface  
226 and functional data were overlaid.

## 227 Voxel selection and analysis

228 Excessive subject movement between runs is likely to affect correspondence between  
229 voxels from one run to another. This could introduce noise into our analysis as we selected our  
230 region of interest (ROI) based on the averaged functional data of all 4 runs. As described  
231 previously (Revina et al., 2018), we calculated an alignment value for each subject by measuring  
232 Pearson's correlation in a ROI in the visual cortex between the four functional runs. Correlations

233 were performed in a ROI covering the early visual cortex using intensity values from an  
234 anatomical representation of the first volume of the functional data of every run. High correlations  
235 would suggest a close anatomical alignment between the 4 runs. The median alignment value  
236 across subjects was 98.08% and single subject values ranged from 77.85% to 99.31%. We excluded  
237 data from further analysis if the alignment value was below 90%, which applied to three subjects.  
238 Furthermore, we excluded any subject with chance level performance in any feedforward  
239 condition in single trial analysis (significance above chance was measured using permutation  
240 analysis with 1000 trials). The feedforward conditions have bottom-up stimulation and hence  
241 there should be a difference in activity patterns. If the scenes could not be decoded in these control  
242 conditions in a subject, we excluded them from the analysis, as it suggests that the subject might  
243 not have been fixating properly, not paying enough attention, falling asleep, and so on. It would  
244 not be meaningful to assess feedback classifier performance (or lack of) in such cases. This  
245 excluded a further five subjects. Thus, the following analyses were performed on 21 subjects.

246 We identified the cortical representation of the occluded region using a general linear  
247 model (GLM) contrast of the *Target* region against the *Near Surround*, as described previously  
248 in Smith & Muckli (2010). The ROI was selected from activation in V1 only. To further minimize  
249 spillover activity from neighbouring stimulated areas, we selected voxels from the ROI on the  
250 basis of the difference between *Target* and *Near Surround* t-values being greater than 1.

### 251 *Analyses with extended boundary around the occluded region*

252 To further make sure our findings of scene information in the quadrant were not due to  
253 spillover activity from the feedforward surround, we performed a separate analysis with more  
254 stringent methods of voxel selection. First of all, we selected our region of interest in BrainVoyager  
255 as the contrast of the *Target* mapping region being higher than both the *Near Surround* and the  
256 *Inner Border* mapping conditions. In addition, we selected voxels fitting the criteria of  $(Target -$   
257  $Near Surround) > 1$  and  $(Target - Inner Border) > 1$ . This helped to restrict voxels to the more  
258 peripheral regions and to further minimize any voxels at the inner borders of the quadrant.  
259 Analysis showed the same pattern of results and significant decoding between the two scenes in

260 all conditions except Small Bubbles Feedback and Full Feedback (average block analysis,  
261 Experiment 1 only).

262 Moreover, we performed another analysis using population receptive field (pRF, Dumoulin  
263 and Wandell, 2008) mapping for the subjects which had both the polar angle and eccentricity  
264 retinotopic mapping available (Expt 2: n = 4, Expt 3: n = 2, Expt 4: n = 4). Again, this was done  
265 to restrict our voxel selection to the quadrant. We only included voxels that were both within the  
266 occluded region as defined by pRF and only within our original *Target > Near Surround* ROI as  
267 defined in BrainVoyager.

### 268 Multivariate Pattern Classification Analysis

269 The voxels matching all the above-mentioned criteria for each analysis were entered into  
270 the linear classifier (Support Vector Machine [SVM], using the LIBSVM toolbox in MATLAB,  
271 Chang and Lin, 2001). For classification analyses, we trained the classifier to decode between the  
272 2 scenes in each condition. For cross-classification analyses we trained the classifier to decode  
273 between the two scenes on one condition and tested on the other. The classifier used single trial  
274 activity patterns (beta values) for training, and was then tested on either “single trial” (ST; 8 trials  
275 × 4 sequences = 32 separate trials) or “average block” (AB) activity patterns for each of the 8 trial  
276 types (average of the 4 repetitions). In other words, for the average block analysis, the training  
277 was the same (single trials of three runs, 32 trials in each run) but the testing was done on the  
278 average per stimulus condition of the fourth run. For both types of analyses, we trained the  
279 classifier on 3 of the runs and tested on the remaining run (i.e. one-run-out cross-validation).

280 In order to get a robust average and to test how well the classifier would perform when the  
281 labels were randomly assigned (described in more detail in Revina et al. 2018), we used  
282 bootstrapping and permutation analysis. We bootstrapped the classifier performances 10000  
283 times for individual subjects (there were four performances for each condition for each subject  
284 due to the one-run-out method on the four runs), to estimate the single subject mean. We then  
285 bootstrapped these mean values from individual subjects 10000 times to estimate 95% confidence

286 intervals (CIs) on the group mean. We counted classifier performances as significantly above  
287 chance (50%) if the 95% CIs did not contain chance-level performance. We used a permutation  
288 test (1000 samples) to compute differences between mean group classifier performances  
289 (reported  $p$  values not corrected for multiple comparisons), by shuffling the observed values  
290 across the conditions, and calculating the absolute differences between the conditions. If the  
291 observed difference was in the top 5% of the differences distribution, we considered our  
292 conditions to be significantly different from each other.

## 293 Results

294 Our hypothesis is that the surround stimulation drives higher visual areas with larger  
295 receptive fields to send a contextual feedback signal to voxels in V1 responding to the occluded  
296 quadrant. We can therefore modify the surround stimulation to learn more about the nature of  
297 contextual feedback.

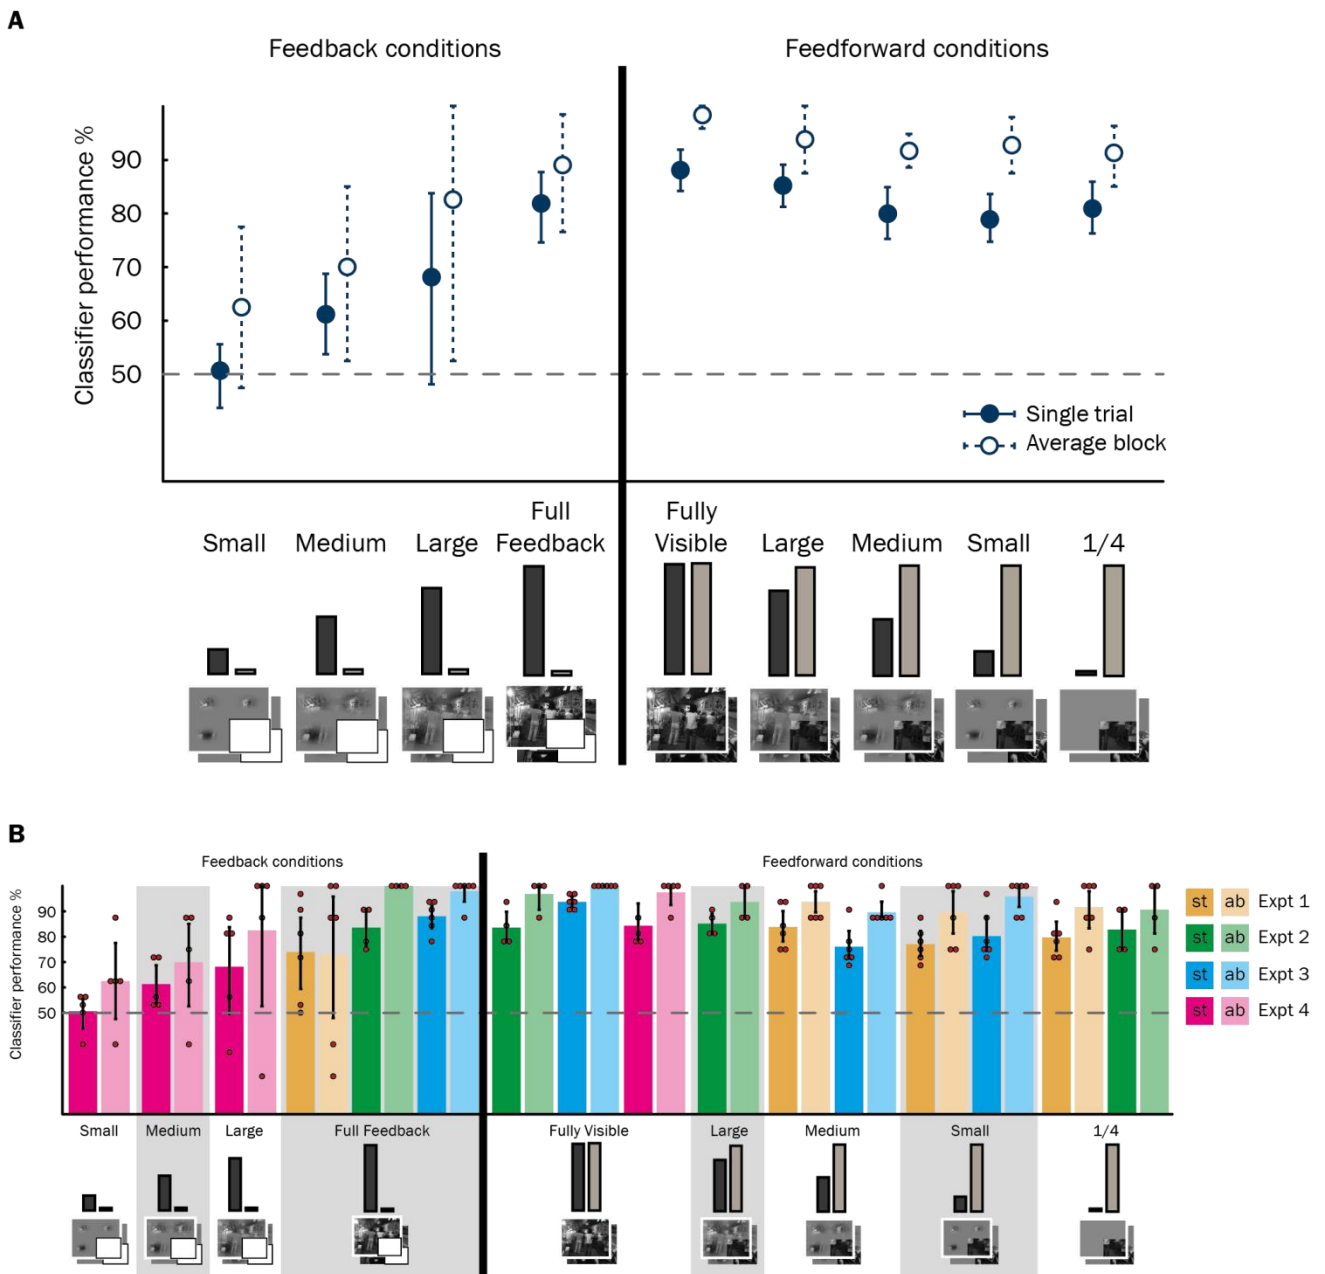

### 298 **Increased stimulation of the surround receptive field enhances contextual feedback**

299 We have shown previously that scene features eliciting contextual feedback to non-  
300 stimulated V1 are not only those features located nearest to the occluded region of the image  
301 (Smith and Muckli 2010). That is, voxels contributing information to scene classification are not  
302 only found near the border of the occluder (Morgan et al., 2019). This finding suggests that scene  
303 classification in non-stimulated voxels is not only related to short-range lateral connections.  
304 Expanding on these findings, we assessed the amount of surrounding scene information required  
305 to elicit scene-relevant information in non-stimulated V1. We parametrically modulated the  
306 availability of surround information and trained the SVM classifier to decode between the two  
307 scenes using voxel patterns responding to the lower right quadrant when it was either occluded  
308 (feedback and lateral, but no feedforward information) or stimulated (feedforward, feedback and  
309 lateral information). SVM classification performance was used as an estimate of the amount of  
310 available information in the activation pattern.

311 When the image was occluded, scene classification in non-stimulated voxels improved with  
 312 increasing availability of surrounding scene information (**Figure 2A**, left). Averaging across  
 313 experiments, classification was significantly above chance once the bubbles exceeded the smallest  
 314 size, except for Large Bubbles Single Trial analysis (**Table 1**). Classifier performance for the Full  
 315 Feedback condition was significantly higher than the Small or Medium Bubbles conditions  
 316 (Small: ST:  $p < 0.001$ ; AB:  $p = 0.015$ ; Medium: ST only:  $p = 0.009$ ). Increased surround  
 317 information also improved classifier performance during feedforward processing of the scenes  
 318 (**Figure 2A**, right), even though voxels received identical feedforward stimulation. The Fully  
 319 Visible condition was significantly higher than the other feedforward conditions (Large: AB only,  
 320  $p = 0.019$ ; Medium: ST:  $p = 0.028$ , AB:  $p = 0.001$ ; Small: ST only,  $p = 0.007$ ; 1/4: ST:  $p = 0.034$ ,  
 321 AB:  $p = 0.017$ ). Classification performance for individual experiments is shown in **Figure 2B**.

322 **Table 1.** Classification performance for decoding between the two scenes in each condition, for feedback and  
 323 feedforward stimuli, averaged across experiments.

	Single trial classification	Confidence interval	Average block classification %	Confidence interval
<u>Feedback</u>				
325	Small Bubbles	50.62	0.0687	0.0500
326	Medium Bubbles	61.25	0.0750,	0.0750
	Large Bubbles	68.13	0.1875,	0.1563
327	Full Feedback	81.84	0.0723,	0.0586
<u>Feedforward</u>				
328	Fully Visible	88.12	0.0396,	0.0375

331 **Figure 2.** Classification performance for decoding between the two scenes in each condition, for feedback and  
 332 feedforward stimuli. Chance level is 50%. Lines represent 95% confidence intervals around the bootstrapped mean  
 333 (10000 bootstrap samples of individual subjects' performances). Classifier performance is significantly above chance  
 334 at  $\alpha = 0.05$  (not corrected for multiple comparisons) if the confidence intervals do not intersect with the chance line.  
 335 A) Classifier performance for each condition, averaged over the four experiments (solid line = classifier tested on  
 336 single trials; dashed line = classifier tested on blocks of conditions averaged over the same type). Small, Medium  
 337 and Large Feedback conditions,  $n = 5$ ; Full Feedback,  $n = 16$ ; Fully Visible,  $n = 15$ ; Large Feedforward,  $n = 4$ , Medium  
 338 and Small Feedforward,  $n = 12$ ;  $\frac{1}{4}$ ,  $n = 10$ . B) Same data as in (A) but classifier performance split by four experiments  
 339 (separate colours). ST (dark hues) show performance when classifier was tested on single trials; AB (light hues)  
 340 when tested on blocks of conditions averaged over the same type. Red circles represent individual subjects' results.

### 341 Contextual feedback enhances feedforward processing

342 Classifier analyses so far reveal that increased presence of the surrounding scene enhances  
 343 scene-specific information in non-stimulated V1. This finding is consistent with the hypothesis  
 344 that part of V1 neuronal information patterns comprises feedback signals from areas with larger

345 receptive fields higher up in the visual hierarchy. Interestingly, feedforward information was also  
346 enhanced with increased surround stimulation. Observing informative feedback signals with and  
347 without feedforward input motivates the question: do feedback and feedforward signals carry the  
348 same information? We used a cross-classification approach to test if the classifier can discriminate  
349 the two scenes in the feedback conditions and then use this information to discriminate scenes in  
350 the feedforward condition. Successful cross-classification would suggest similar information  
351 content in feedforward and feedback signals.

352 How much does feedback contribute to visual processing?

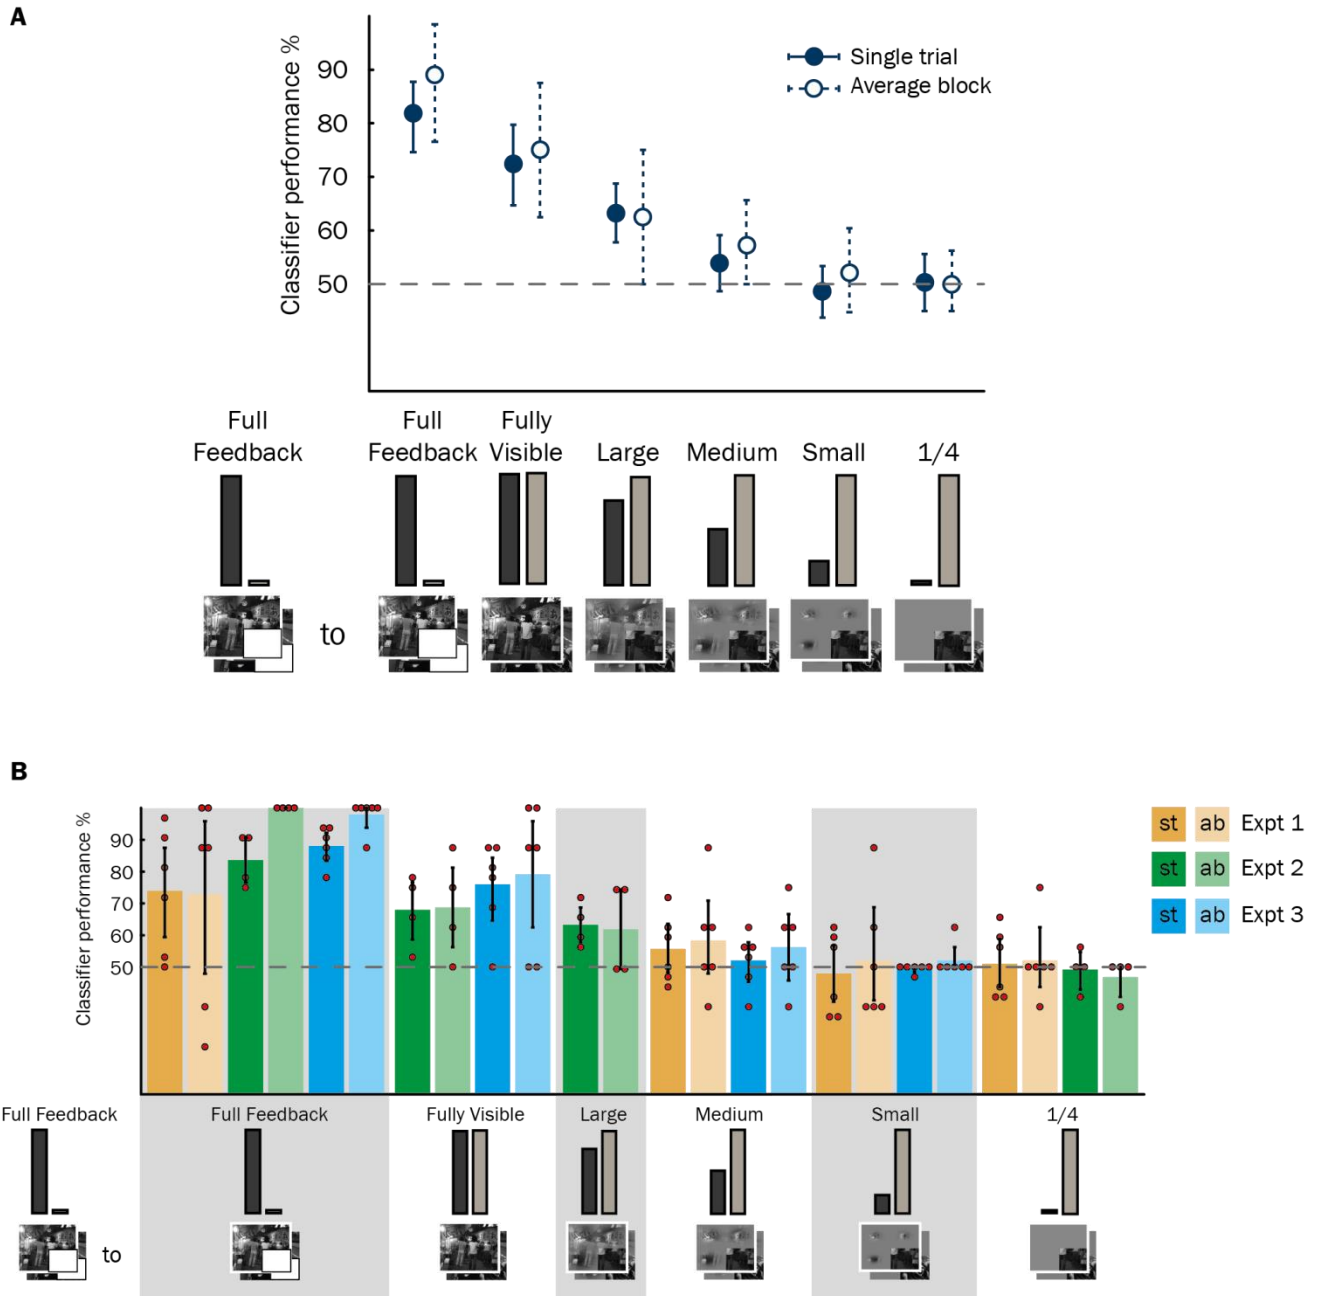

353 We trained the classifier to decode between the two scenes in the Full Feedback condition  
354 (with no direct feedforward input in the quadrant) and tested on the feedforward conditions, with  
355 varying amount of feedback from the surround (**Figure 3**). Cross-classification performance  
356 decreased with decreasing scene information in the surround. The classifier could generalize from  
357 the Full Feedback condition to the Fully Visible and Large Bubbles condition (ST only; **Figure**  
358 **3A** and **Table 2**). However, cross-classification for Medium, Small Bubbles, and  $\frac{1}{4}$  conditions  
359 was at chance level. Averaging across experiments (**Figure 3A**), the Fully Visible condition was  
360 significantly higher than the Medium Bubbles (ST:  $p = 0.002$ ; AB:  $p = 0.021$ ), Small Bubbles (ST:  
361  $p < 0.001$ ; AB:  $p < 0.001$ ) and the  $\frac{1}{4}$  condition (ST:  $p < 0.001$ ; AB:  $p = 0.003$ ). These results tell  
362 us that we can train on a feedback signal (that likely has a coarser resolution of information), and  
363 test on a signal that is a combination of fine-grained feedforward signal and (coarse) surround  
364 feedback signal. This cross-classification must be due to the contextual feedback signal rather  
365 than shared information between feedforward and feedback because when the surround stimulus  
366 is reduced to nothing (i.e. with shrinking bubbles), we learn that the content of information or its  
367 scale (coarse or fine) in feedforward and feedback signals differs.

368

369 **Table 2.** Cross-classification performance for training on the Full Feedback condition and testing on the feedforward  
 370 conditions, averaged across experiments.

371		Single trial classification	Confidence interval	Average block classification %	Confidence interval
372	Fully Visible	72.50	0.0781, 0.0750	75.00	0.1125, 0.1125
	Large Bubbles	63.28	0.0547, 0.0547	62.50	0.1250, 0.1250
373	Medium Bubbles	53.91	0.0521, 0.0495	57.29	0.0729, 0.0833
	Small Bubbles	48.70	0.0495, 0.0469	52.08	0.0625, 0.0833
	1/4	50.31	0.0500, 0.0531	50.00	0.0500, 0.0625

374

375 **Figure 3.** Cross-classification performance for training on the Full Feedback condition and testing on the feedforward  
 376 conditions. Chance level is 50%. Lines represent 95% confidence intervals around the bootstrapped mean.  
 377 Classification performance for the Full Feedback stimulus (training and testing on the same condition) is shown for  
 378 comparison. Classifier performance is significantly above chance at  $\alpha = 0.05$  (not corrected for multiple comparisons)  
 379 if the confidence intervals do not intersect with the chance line. A) Classifier performance for each condition, averaged  
 380 over the four experiments (solid line = classifier tested on single trials; dashed line = classifier tested on blocks of  
 381 conditions averaged over the same type). Fully Visible,  $n = 10$ ; Large,  $n = 4$ ; Medium and Small,  $n = 12$ ; 1/4,  $n = 10$ .  
 382 B) Same data as in (A) but classifier performance split by four experiments (separate colours). ST (dark hues) show  
 383 performance when the classifier was tested on single trials; AB (light hues) when tested on blocks of conditions  
 384 averaged over the same type. The small red circles represent individual subjects' results.

385

386

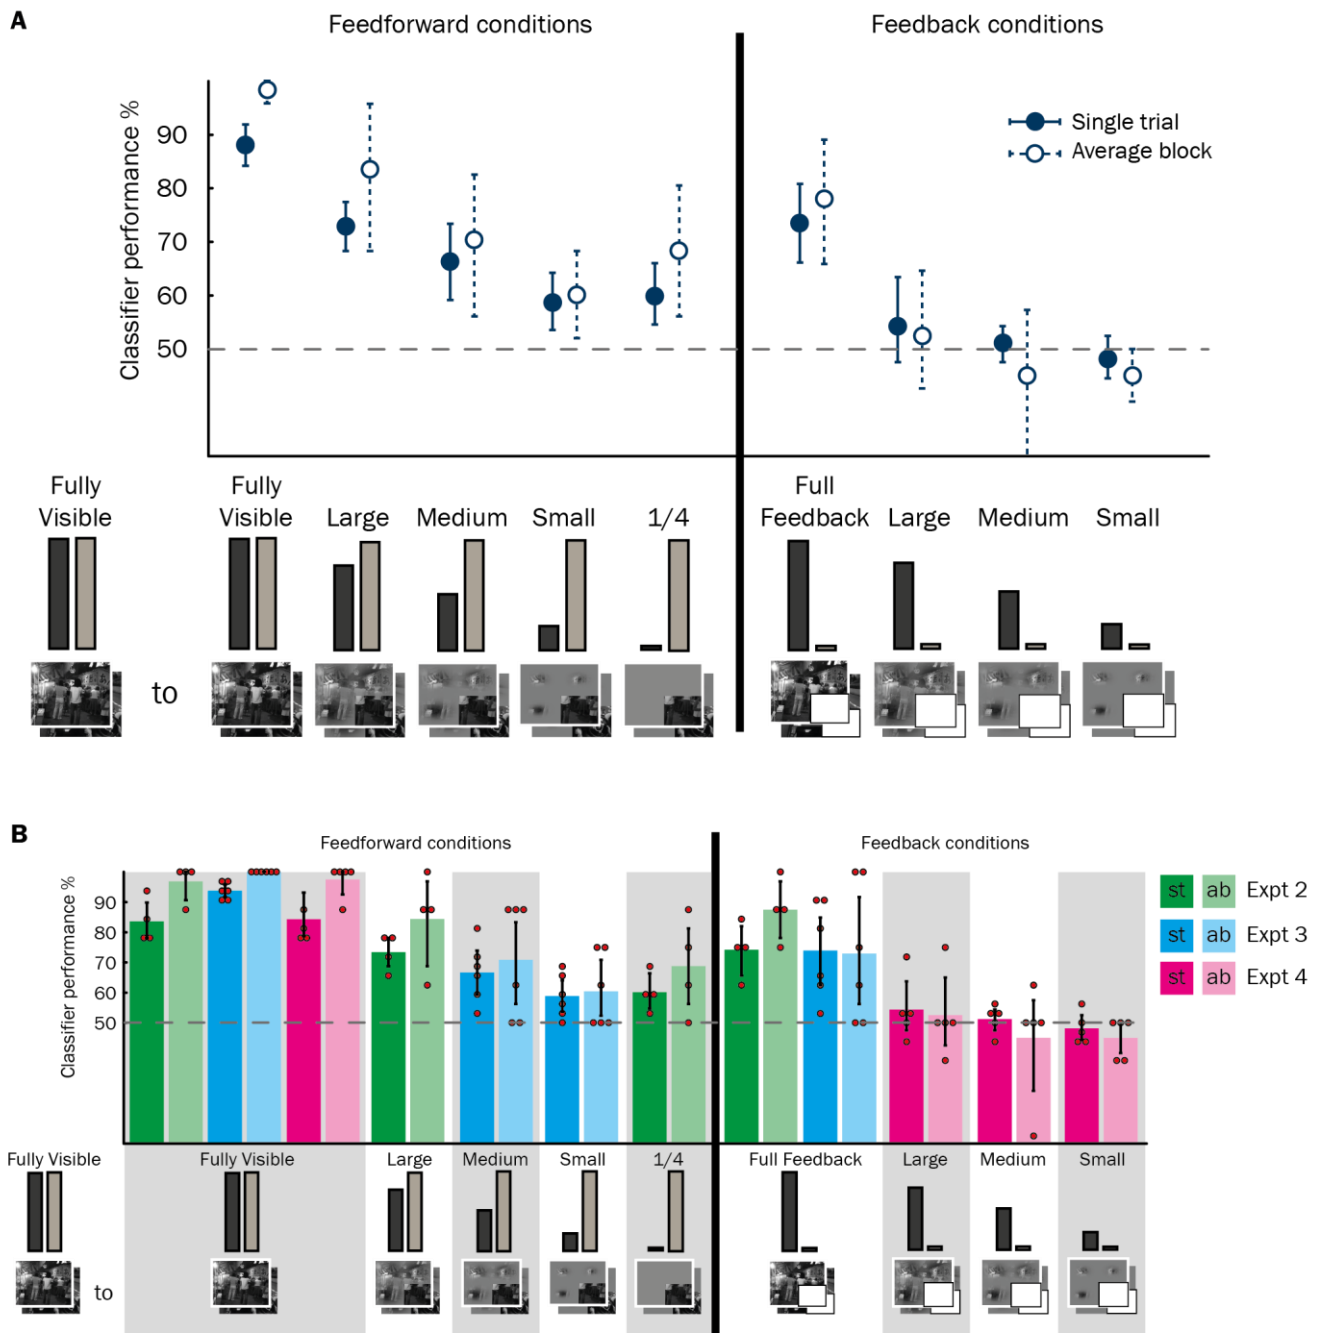

387

To further test how much surround information contributes to visual processing, we compared the Fully Visible scene with other feedforward conditions with a reduced scene surround, as well as the feedback conditions (**Figure 4**). We trained the classifier on the Fully

388 Visible scene and tested on the other conditions. In a fully visible scene both parts of the  
 389 information are available simultaneously and the classifier might rely more on the rich, fine-  
 390 grained feedforward information. However, we found that Fully Visible feedforward to feedback  
 391 cross-classification was only possible with large amounts of scene information surrounding the  
 392 occluded region (**Table 3**). Fully Visible to Full Feedback cross-classification was above chance,  
 393 while Large, Medium and Small Bubbles did not reach significance in the feedback conditions. In  
 394 addition, although we could cross-classify above chance from the Fully Visible to all other  
 395 feedforward conditions, cross-classification reduced with decreased scene information in the  
 396 surround. Classifier performance was significantly higher for Large Bubbles compared to Small  
 397 Bubbles (ST:  $p = 0.007$ ; AB:  $p = 0.023$ ) and  $1/4$  (ST only:  $p = 0.028$ ) conditions. If contextual  
 398 feedback did not contribute scene-specific information to V1, we would have observed equal cross-  
 399 classification across feedforward conditions, regardless of surround stimulation. This suggests  
 400 that much of the information in the activity patterns of the Fully Visible scene comes from  
 401 feedback from the surround.

402 **Table 3.** Cross-classification performance for training the classifier on the Fully Visible scene and testing on the other  
 403 feedforward and feedback conditions, averaged across experiments.

	Single trial classification	Confidence interval	Average block classification %	Confidence interval
<u>Feedforward</u>				
Large Bubbles	73.44	0.0469, 0.0469	84.38	0.1563, 0.1250
Medium Bubbles	66.67	0.0729, 0.0729	70.83	0.1458, 0.1250
Small Bubbles	58.85	0.0521, 0.0573	60.42	0.0833, 0.0833
$1/4$	60.16	0.0547, 0.0625	68.75	0.1250, 0.1250
<u>Feedback</u>				
Full Feedback	74.06	0.0750, 0.0750	78.75	0.1250, 0.1125
Large Bubbles	54.37	0.0687, 0.0938	52.50	0.1000, 0.1250
Medium Bubbles	51.25	0.0375, 0.0313	45.00	0.1750, 0.1250

410

411 **Figure 4.** Cross-classification performance for training the classifier on the Fully Visible scene and testing on the  
 412 other feedforward and feedback conditions. Chance level is 50%. Lines represent 95% confidence intervals around  
 413 the bootstrapped mean. Classification performance for the Fully Visible stimulus (training and testing on the same  
 414 condition) is shown for comparison. Classifier performance is significantly above chance at  $\alpha = 0.05$  (not corrected  
 415 for multiple comparisons) if the confidence intervals do not intersect with the chance line. A) Classifier performance  
 416 for each condition, averaged over the four experiments (solid line = classifier tested on single trials; dashed line =  
 417 classifier tested on blocks of conditions averaged over the same type). Large Feedforward,  $n = 4$ ; Medium and Small  
 418 Feedforward,  $n = 6$ ;  $\frac{1}{4}$ ,  $n = 4$ ; Full Feedback,  $n = 10$ ; Large, Medium and Small Feedback,  $n = 5$ . B) Same data as in  
 419 (A) but classifier performance split by four experiments (separate colours). ST (dark hues) show performance when  
 420 the classifier was tested on single trials; AB (light hues) when tested on blocks of conditions averaged over the same  
 421 type. The small red circles represent individual subjects' results.

422

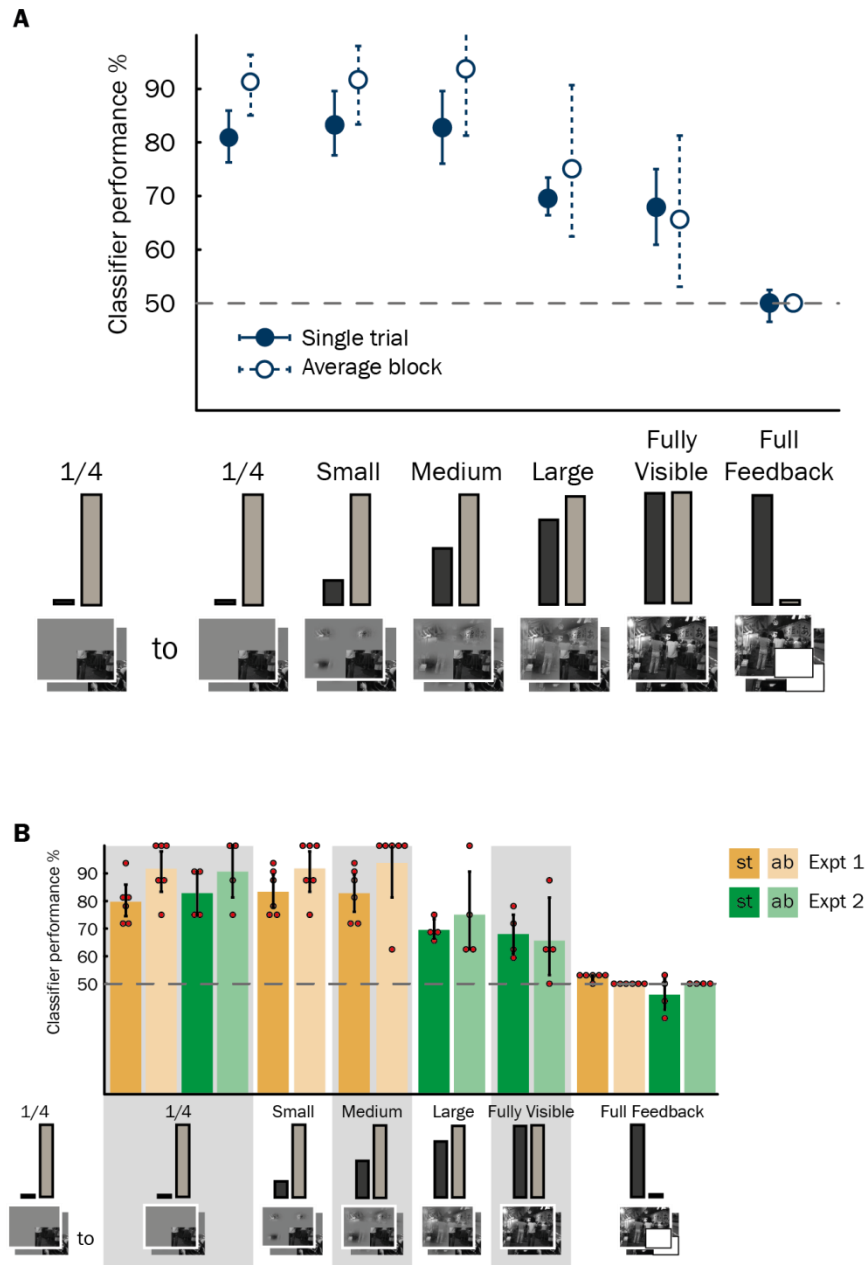

423 Interestingly, we found that when the classifier was trained on the Fully Visible image  
 424 (**Figure 4**) it cross-classified better to Full Feedback than to feedforward conditions in which the

425 feedback was restricted by reduced contextual information (significantly above chance for Small  
426 Bubbles: ST:  $p = 0.013$ ; AB:  $p = 0.035$ ). This suggests that feedback in the occluded region from  
427 full stimulation in the surround is at least as informative about the scene as feedforward  
428 information in the quadrant with minimal surround stimulation. This shows that feedback is an  
429 important part of the information in V1, both when feedforward stimulation is present and when  
430 it is absent.

431 If surround feedback information interacts with feedforward processing, then increasing  
432 contextual surround information should reduce cross-classification from the  $\frac{1}{4}$  feedforward  
433 condition to feedforward conditions with surround stimulation (**Figure 5**). Indeed, cross-  
434 classifier performance for  $\frac{1}{4}$  to Small Bubbles (**Table 4**) was higher than to Large (ST only:  $p =$   
435  $0.015$ ) or the Fully Visible condition (ST:  $p = 0.021$ ; AB:  $p = 0.006$ ). Cross-classifier performance  
436 for  $\frac{1}{4}$  to Medium Bubbles was also significantly higher than to Large (ST only:  $p = 0.039$ ) or the  
437 Fully Visible condition (ST:  $p = 0.037$ ; AB:  $p = 0.036$ ).

438 **Table 4.** Cross-classification performance for training the classifier on the  $\frac{1}{4}$  and testing on the other feedforward  
439 conditions, averaged across experiments.

	Single trial classification	Confidence interval	Average block classification %	Confidence interval
Small Bubbles	83.33	0.0573, 0.0625	91.67	0.0833, 0.0625
Medium Bubbles	82.81	0.0677, 0.0677	93.75	0.1250, 0.0625
Large Bubbles	69.53	0.0313, 0.0391	75.00	0.1250, 0.1563
Fully Visible	67.97	0.0703, 0.0703	65.63	0.1250, 0.1563

440

441 **Figure 5.** Cross-classification performance for training the classifier on the  $\frac{1}{4}$  condition and testing on the other  
 442 feedforward and feedback conditions. Chance level is 50%. Lines represent 95% confidence intervals around the  
 443 bootstrapped mean. Classification performance for the  $\frac{1}{4}$  stimulus (training and testing on the same condition) is  
 444 shown for comparison. Classifier performance is significantly above chance at  $\alpha = 0.05$  (not corrected for multiple  
 445 comparisons) if the confidence intervals do not intersect with the chance line. A) Classifier performance for each  
 446 condition, averaged over the four experiments (solid line = classifier tested on single trials; dashed line = classifier  
 447 tested on blocks of conditions averaged over the same type). Small and Medium,  $n = 6$ ; Large and Fully Visible,  $n =$   
 448  $4$ ; Full Feedback,  $n = 10$ . B) Same data as in (A) but classifier performance split by four experiments (separate  
 449 colours). ST (dark hues) show performance when the classifier was tested on single trials; AB (light hues) when  
 450 tested on blocks of conditions averaged over the same type. The small red circles represent individual subjects'  
 451 results.

452 Does increased presentation of the entire image change feedback information?

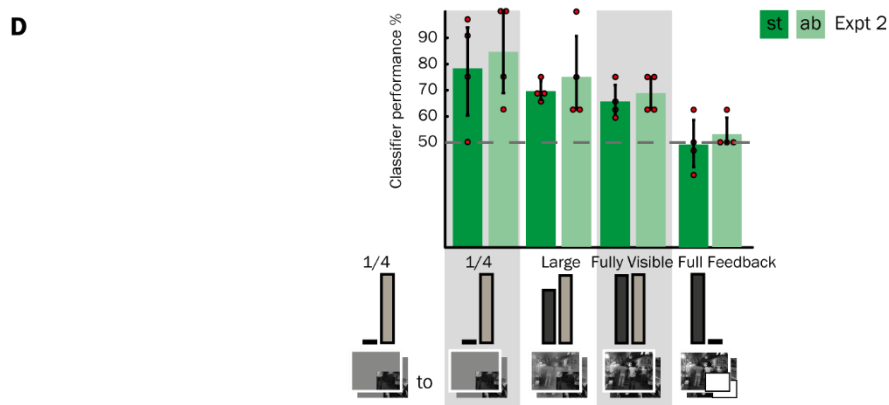

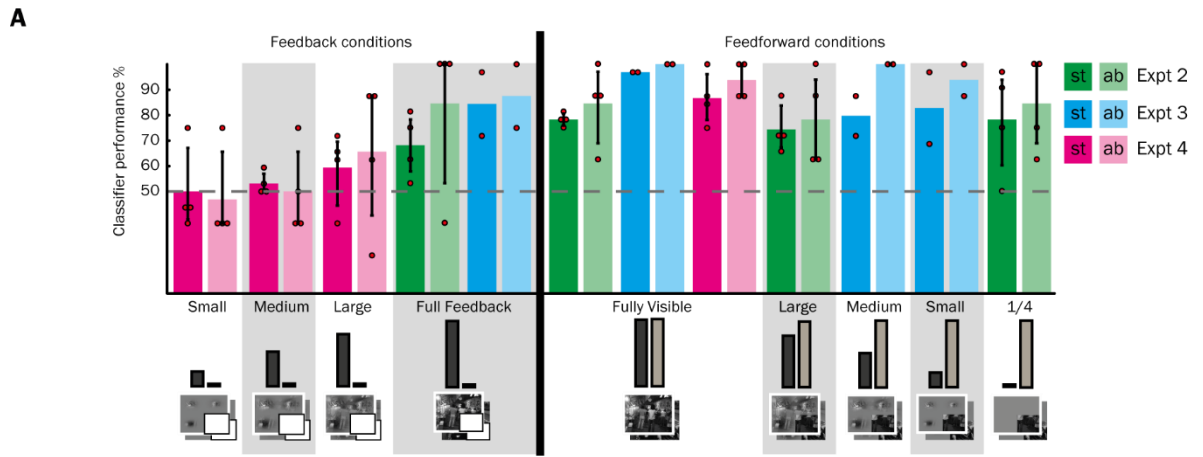

453 Apart from varying how much surround information is visible in a stimulus, we also  
 454 investigated whether knowledge of the full scene would improve feedback in the stimuli with  
 455 reduced surround. In Experiment 3, we presented the Fully Visible scenes along with the Medium

456 and Small Bubbles stimuli, unlike in Experiment 1 where we had not presented the Fully Visible  
457 scene as one of the stimuli (although all subjects were shown the full scenes in a practice run prior  
458 to the experimental session). Varying the frequency of the Fully Visible scene allowed us to  
459 investigate whether being presented with the full structure of the scene (during the experimental  
460 run) would boost meaningful feedback in stimuli with reduced surround information. We found  
461 that cross-classification from Full Feedback to Small and Medium Bubbles was at chance level for  
462 both Experiment 1 and 3 (**Figure 3B**), suggesting that reduced feedback to the feedforward  
463 quadrant in the Small and Medium Bubbles stimuli was mainly due to the decreased contextual  
464 surround information in the stimulus as opposed to a reduced implicit memory of the fully visible  
465 scene.

#### 466 **Results with extended safety boundary around occluded region**

467 We performed an additional separate analysis in order to decrease the number of voxels  
468 that are close to the boundary region and hence reduce the possibility of any feedforward  
469 stimulation “spilling over” from the surround. For the conjunction analysis using the contrast of  
470 (*Target > Near Surround*) & (*Target > Inner Border*), we found the same pattern of results and  
471 significant decoding between the two scenes in all conditions except Small Bubbles Feedback, and  
472 Full Feedback (AB analysis, Experiment 1 only).

473 After restricting voxels to the occluded region using pRF mapping, we saw that classifier  
474 performance decreased in some conditions, but the pattern of the results remained the same  
475 (**Figure 6**). Due to the low numbers of subjects in each experiment for whom we were able to  
476 perform pRF mapping, we did not calculate confidence intervals for some of the mean values.

478 **[Previous page] Figure 6.** Classification and cross-classification performance after applying population receptive  
479 field (pRF) mapping to further constrain voxels to the occluded region. Classifier performance is shown for each  
480 condition for each of the three experiments (separate colours; Expt 2: n = 4; Expt 3: n = 2; Expt 4: n = 4). ST (dark  
481 hues) show performance when the classifier was tested on single trials; AB (light hues) when tested on blocks of  
482 conditions averaged over the same type. The small red circles represent individual subjects' results. Chance level is  
483 50%. A) Decoding two scenes in the same condition. B) Training on Full Feedback and testing on feedforward  
484 conditions. C) Training on the Fully Visible scene and testing on other feedforward and feedback conditions. D)  
485 Training on the  $\frac{1}{4}$  condition and testing on other feedforward and feedback conditions.

486

## 487 Discussion

488 We studied the influence of the scene surround on populations of neurons using fMRI,  
489 complementing what we know from electrophysiology studies investigating classical and non-  
490 classical neuronal receptive fields. We established that the availability of contextual information  
491 affects cortical feedback to a non-stimulated region in V1. Specifically, the extent of contextual  
492 modulation in non-stimulated V1 depends on the amount of scene information surrounding the  
493 occluded image quadrant. Furthermore, information in the non-stimulated region does not  
494 represent a direct filling-in of missing feedforward input, and that contextual feedback enhances  
495 information in V1 even when rich feedforward information is available.

496 V1 neurons integrate signals over a large area beyond the classical receptive field  
497 (Angelucci et al., 2002; Angelucci and Bressloff, 2006). Lateral connections modulate the  
498 response in the central receptive field over short distances. However, feedback from higher areas  
499 accounts for the full extent of the surround modulation effects (Angelucci and Bressloff, 2006).  
500 There was no meaningful feedforward stimulation in our occluded region of V1, and yet we could  
501 decode two scenes using information patterns corresponding to this non-stimulated region. This  
502 differential information must originate from contextual information in the scene surround.  
503 Classical receptive fields are smaller than the surround, hence neurons in the occluded area in V1  
504 most likely receive information about the rest of the scene via cortical feedback from higher areas.  
505 Since we are measuring a population of neurons using fMRI, as opposed to single cells, it is hard  
506 to estimate how widespread the effect of the surround receptive field is. V1 receives feedback from  
507 many cortical areas, which have increasing receptive field sizes moving to higher and more  
508 abstract processing areas (Dumoulin and Wandell, 2008). Therefore, we expect that influence

509 from the surround might be restricted to regions close to the occluded region for feedback coming  
510 from V2, for example, but transmit information from a larger area of the surrounding scene for  
511 feedback originating from higher visual areas.

512 We found that larger bubbles in the surround lead to more informative feedback in the  
513 occluded region. This may be because we are revealing more of the overall scene structure as we  
514 increase the bubble size. Tang and colleagues (2014) demonstrated top-down effects in image  
515 completion by presenting partially revealed images using bubbles. The number of bubbles was  
516 constant, but their location was changed. This suggests that revealing a certain amount of the  
517 global image structure, regardless of the specific parts, can be enough for top-down completion  
518 to take effect. Alternatively, our result could be explained by larger bubbles providing more  
519 information close to the lower right quadrant, compared to small bubbles, because our bubbles  
520 were centred in each quadrant. However, Williams and colleagues (2008) have demonstrated that  
521 feedback can come from distant retinotopic regions, by showing that the fovea receives feedback  
522 about objects in the periphery. Since we did not specifically measure effects of bubble location, it  
523 remains to be seen how varying proximity of surrounding information affects feedback  
524 information in non-stimulated V1. It also remains to be seen how contextual feedback depends on  
525 the presence of task-specific diagnostic features that could be revealed on different trials using  
526 bubbles (Gosselin and Schyns, 2001). Subsets of stimulus features drive information states of  
527 functionally-relevant higher brain regions (e.g. face areas) during the feedforward sweep of visual  
528 processing (e.g. Schyns et al., 2007) and these representations could modulate the content of  
529 cortical feedback signals. For the purpose of this study we kept these parameters constant.

### 530 **Interaction of feedback and feedforward signals**

531 We found that stimulating the surround increased information in both the occluded region  
532 and when it contains feedforward information. Similarity between identical feedforward  
533 quadrants was reduced if the amount of information in the surround was increased. If feedback  
534 signals from the surround did not combine with feedforward information or only weakly  
535 modulated it, we would have seen similar activity patterns relating to the feedforward quadrant

536 regardless of the surround. The feedforward signal has been traditionally considered the  
537 dominant signal, since it drives receptive fields, while feedback has been thought of mostly  
538 modulatory and not necessarily able to trigger spikes (Bullier, 2006; Bastos et al., 2012), but see  
539 Mignard and Malpeli, (1991). By using fMRI which is also sensitive to non-spiking activity  
540 (Logothetis, 2008; Muckli, 2010) we established that this modulation from feedback may be just  
541 as important as the spiking produced by stimuli in a bottom-up manner. fMRI is sensitive to  
542 postsynaptic inputs including the arrival of feedback onto the apical dendrites. Feedback can be  
543 combined with feedforward inputs arriving to the basal dendrites, meaning that individual  
544 neurons integrate internally-generated feedback signals with sensory-derived feedforward signals  
545 (Larkum, 2013), a process which might be a cornerstone of conscious perception (Phillips et al.,  
546 2016). Though this neuronal mechanism remains to be observed in the visual cortex, many studies  
547 support the notion that feedback to V1 is a crucial part of visual perception. For example, reducing  
548 feedback from higher areas such as V2, MT or hMT reduces the neuronal response the lower areas  
549 to visual stimulation in the centre RF, (Sandell and Schiller, 1982; Hupé et al., 1998, 2001;  
550 Schmidt et al., 2011) and in humans affects prediction in an apparent motion paradigm (Vetter et  
551 al., 2015).

## 552 **Information content of feedback**

553 Predictive coding theories (Rao and Ballard, 1999; Friston, 2010; Clark, 2013) hypothesise  
554 that the occluded part of our scenes should be represented in non-stimulated cortex, based on the  
555 expected scene structure behind the occluder. Several authors have demonstrated that an  
556 expected or predicted stimulus evokes activity in V1 which is similar to activity elicited by actual  
557 bottom-up stimulation (e.g. Ban et al., 2013; Gavornik and Bear, 2014; Kok et al., 2014).  
558 Therefore, at first glance, it is surprising that we do not find similarity between the occluded  
559 region and the missing feedforward quadrant. This suggests information in feedback signals does  
560 not represent a direct filling-in of the missing feedforward input. However, a lack of a direct  
561 filling-in is not so counter-intuitive since participants do not report seeing the missing portion of  
562 the scene in occluded trials (i.e. they do not have a hallucination). Hence feedback and

563 feedforward information may be coded in different formats, even though both carry information  
564 about the scene. For example, it may be that information is coarser in terms of its content because  
565 of the larger visual fields in higher visual areas or less precise retinotopically (e.g. de-Wit et al.,  
566 2012). Alternatively, feedback may provide a more abstract version of the scene. In a previous  
567 study, we have shown that feedback information is comparable to a line drawing completing the  
568 missing quadrant (Morgan et al., 2019). Finally, a difference in neural patterns could be observed  
569 because feedback and feedforward signals project to different cortical layers (Rockland and Virga,  
570 1989; Muckli et al., 2015). Muckli and colleagues (2015) showed using high-resolution fMRI that  
571 during normal visual stimulation, feedforward information peaks in mid-layers of V1, while  
572 contextual feedback information peaks in the superficial layers. Recent data from neural network  
573 modelling also suggests that recurrent processing is not completing or filling-in the information  
574 to make it identical to the feedforward response, but rather it may function by suppressing  
575 occluders and enhancing responses to the hidden target (Spoerer et al., 2017). Recurrent networks  
576 also outperform feedforward models in identifying the occluded target stimulus, suggesting that  
577 feedback enhances feedforward processing.

578         If feedback signals are carrying expectations and predictions based on prior knowledge we  
579 might find that improved knowledge of the full scene structure would be important for meaningful  
580 feedback in the occluded region. However, it seems that knowledge about the particular scene  
581 being viewed is not necessary. Smith and Muckli (2010) previously found that contextual feedback  
582 in the occluded region is present even if participants never see the fully visible scene and were not  
583 familiarised with it. We also found that increased exposure to the full scene did not improve  
584 feedback in the conditions with reduced surround. Therefore, it appears that the contextual  
585 feedback we observed arises from the scene structure available in each trial, or knowledge of  
586 natural scene properties in general, but familiarity with the specific scene is not required for  
587 informative feedback signals. This could be because natural scenes have predictable scene  
588 statistics and much of the information they contain is redundant (e.g. Attneave, 1954; Barlow,  
589 1961; Torralba and Oliva, 2003).

## 590 **Conclusion**

591 We demonstrated that cortical feedback information forms a part of early visual cortex  
592 activity during visual stimulation. Using a brain imaging technique we have corroborated  
593 evidence from animal electrophysiology showing that stimulation in the far-surround receptive  
594 field modulates responses in the classical visual receptive field. We show that increased  
595 information in the scene surround results in increased scene information in both stimulated and  
596 non-stimulated visual field regions. We conclude that cortical feedback carries abstract internal  
597 models of natural scenes which are combined with more spatially-specific, detailed  
598 representations in primary visual cortex, and that the merging of high-level content of cortical  
599 feedback with feedforward signals should constrain our understanding of cortical function during  
600 perception.
