## 19 **Abstract**

20 Detection of repeating patterns within continuous sound streams is crucial for efficient auditory  
21 perception. Previous studies demonstrated a remarkable sensitivity of the human auditory system to  
22 periodic repetitions in randomly generated sounds. Automatic repetition detection was reflected in  
23 different EEG markers, including sustained activity, neural synchronisation, and event-related  
24 responses to pattern occurrences. The current study investigated how listeners' attention and the  
25 temporal regularity of a sound modulate repetition perception, and how this influence is reflected in  
26 different EEG markers that were previously suggested to subserve dissociable functions. We  
27 reanalysed data of a previous study in which listeners were presented with random acoustic  
28 sequences with and without repetitions of a certain sound segment. Repeating patterns occurred  
29 either regularly or with a temporal jitter within the sequences, and participants' attention was  
30 directed either towards or away from the auditory stimulation. Across both regular and jittered  
31 sequences during both attention and in-attention, pattern repetitions led to increased sustained  
32 activity throughout the sequence, evoked a characteristic positivity-negativity complex in the event-  
33 related potential, and enhanced inter-trial phase coherence of low-frequency oscillatory activity  
34 time-locked to repeating pattern onsets. While regularity only had a minor (if any) influence,  
35 attention significantly strengthened pattern repetition perception, which was consistently reflected  
36 in all three EEG markers. These findings suggest that the detection of pattern repetitions within  
37 continuous sounds relies on a flexible mechanism that is robust against in-attention and temporal  
38 irregularity, both of which typically occur in naturalistic listening situations. Yet, attention to the  
39 auditory input can enhance processing of repeating patterns and improve repetition detection.

## 40 Introduction

41 Detection of repeating patterns is crucial for efficient perception of sounds that continuously  
42 unfold in time (1,2). Especially in complex listening situations that involve several simultaneously  
43 active sound sources, recognition of familiar sound patterns facilitates the segregation of sound  
44 streams and enables rapid adaptive reactions to change in the environment (3–7). There is  
45 compelling evidence that the human auditory system is exceptionally sensitive to pattern repetitions  
46 in sounds, even when the acoustic signal contains only minimal spectro-temporal structure such as  
47 in the case of (periodic) white noise (8–13).

48 Numerous studies have investigated both behavioural and neural correlates of pattern  
49 repetition detection in continuous streams of complex and meaningless sounds, including white  
50 noise (8,13–21), sequences of tone pips (22–29), “tone clouds” (30,31), and “correlated noise” (32).  
51 Besides above-chance behavioural detection of repetitions with a performance that is comparable to  
52 an ideal observer model (22), characteristic changes in several electroencephalography  
53 (EEG)/magnetoencephalography (MEG) markers were found to reflect (automatic) repetition  
54 detection: First, compared with random stimulus sequences (without pattern repetitions), an  
55 increase in magnitude of the sustained response typically occurred relative to the first pattern  
56 repetition within a sequence (22,24,25,27–29). Second, repeating pattern onsets (within the  
57 continuous sound) evoked a characteristic negativity in the event-related potential (ERP;  
58 15,16,18,20,26,33), in some studies preceded by an early positivity (20,26,33). Finally, pattern  
59 repetitions within a sound sequence enhanced inter-trial phase coherence (ITPC) of low-frequency  
60 neural oscillations (relative to sequences without repetitions; 15,16,19,20,25). While in most studies  
61 ITPC may have at least partly reflected a sequence of ERPs evoked by periodically repeating pattern  
62 onsets, there is also evidence for synchronisation of oscillatory activity beyond the frequency of  
63 (isochronous) pattern occurrence in the stimulation (19).

64           A growing number of studies has moved beyond using strictly isochronous pattern  
65 repetitions and asking participants to complete an active repetition detection task. In fact, any  
66 mechanism that can possibly support pattern repetition detection in real-life listening situations  
67 should be somewhat tolerant to listeners' in-attention and temporal irregularity with regard to  
68 pattern occurrence in the stimulus stream. Several studies showed that this is indeed the case: A  
69 negativity in the ERP was elicited relative to the onset a repeating pattern in white noise not only  
70 when participants' attention was focussed on the auditory stimuli, but also when they were  
71 presented with the noise sequences while reading a book (33), performing a visual distractor task  
72 (15), and even during sleep (16). Similarly, pattern repetitions in white noise and sequences of tone  
73 pips led to an increase in ITPC while participants were asleep (16) or focussed on a concurrent visual  
74 task (25). A repetition-related increase in sustained response magnitude to sequences of tone pips in  
75 the absence of listeners' attention to the auditory stimulation was reported by some studies (22,27–  
76 29), but not by others (25). Only one study investigated the role of temporal regularity for the  
77 detection of pattern repetitions in tone pip sequences: Hodapp & Grimm (2021) found that a  
78 negativity time-locked to repeating pattern onsets was elicited consistently across temporally  
79 regular and jittered sequences, whereas the earlier positivity occurred only in regular sequences.  
80 They therefore argued that, while the negative component is related to the repetition of a specific  
81 pattern (irrespective of temporal regularity), the additional positive component in regular,  
82 temporally predictable sequences reflects neural entrainment to the periodic stimulus rhythm and  
83 anticipation of upcoming pattern occurrences (26).

84           Taken together, neither attention nor temporal regularity appears to be indispensable for  
85 the successful detection of repeating patterns in continuous sounds. However, since earlier studies  
86 only focussed on either of the two factors and not always directly compared different levels of  
87 attention or regularity, less is known about the interaction between attention and regularity and  
88 about whether they substantially modulate repetition perception. For instance, it remains unclear  
89 whether irregular repetitions could also be detected in the absence of attention, and whether

90 attention and regularity improve (or in-attention and irregularity impair) the detection of pattern  
91 repetitions. Moreover, previous findings revealed some discrepancy with regard to the influence of  
92 attention on different repetition-related EEG markers (often analysed only in separate studies). One  
93 study analysed both sustained activity and ITPC within the same dataset and found that temporal  
94 regularity of a sound led to an increase of ITPC irrespective of the listeners' attentional state, while  
95 an increase in sustained activity was only observed during attention (but not during in-attention;  
96 Herrmann & Johnsrude, 2018). Therefore, the authors argued that the two markers might reflect  
97 functionally dissociable stages of repetition perception (25). The current study aims to systematically  
98 assess in a two-by-two design how attention and temporal regularity (as well as their interaction)  
99 shape pattern repetition perception and influence its different neural signatures (within the same  
100 dataset). To this end, we presented listeners with sequences of correlated noise that contained (or  
101 did not contain) repetitions of a certain sound segment, with repetitions occurring either in a  
102 temporally regular or jittered manner, while attention was directed either towards or away from the  
103 auditory stimulation. We analysed three different EEG markers that were previously related to  
104 successful repetition detection: global field power (GFP) as a measure of sustained activity  
105 throughout the sequence, ERPs time-locked to repeating pattern onsets, and ITPC. That way, we  
106 might be able to reconcile previous, partly discrepant, findings on the role of attention and regularity  
107 and provide a more comprehensive view on auditory repetition perception and its neural correlates.

108

## 109 **Materials and Methods**

110 The present study is a reanalysis of a dataset that was previously used to explore a different  
111 research question, namely the formation of memories for recurring sound patterns *across* trials (34).  
112 Conversely, the current analysis investigates the perception of pattern repetitions *within* sounds.

## 113 **Participants**

114           29 participants (26 female, three male), aged 18 to 32 years ( $M = 21.38$  years,  $SD = 3.21$   
115 years), took part in the study. None of them reported impaired hearing or a history of any  
116 neurological or psychiatric disorder, and all of them had normal or corrected-to-normal vision.  
117 Participants were recruited at Leipzig University between April and July 2022. All participants were  
118 naïve regarding the purpose of the study, gave written informed consent before the start of the  
119 experiment, and received course credits for their participation. Consent forms were stored  
120 separately from the experimental data, and any personal data were pseudonymised, such that after  
121 data collection individual participants could not be identified. We obtained written approval by a  
122 local ethics committee (Ethics Advisory Board at Leipzig University; reference number:  
123 2022.01.26\_eb\_128) prior to the study, and all experimental procedures were in accordance with  
124 the Declaration of Helsinki.

## 125 **Stimuli**

126           We used sequences of correlated noise as auditory stimulus material. Correlated noise was  
127 described in detail by McDermott and colleagues (2011) and refers to randomly generated white  
128 noise sequences that were transformed using a generative model to match statistical properties of  
129 natural sounds. Stimulus sequences were created using the Gaussian Sound Synthesis Toolbox  
130 ([http://mcdermottlab.mit.edu/Gaussian\\_Sound\\_Code\\_for\\_Distribution\\_v1.1](http://mcdermottlab.mit.edu/Gaussian_Sound_Code_for_Distribution_v1.1)) in Matlab (version  
131 R2021a; The MathWorks Inc., USA), with a duration of 3500 ms, including 5-ms onset and offset  
132 ramps (half-Hanning windows). Transformation of the white noise sequences resulted in correlated  
133 noise sequences with a correlative structure, i.e., adjacent sampling points along the temporal and  
134 spectral dimension were correlated with regard to their spectral energy values, and the strength of  
135 this correlation decreased with increasing distance. Decay constants were the same as in the original  
136 study (-0.065 per 20 ms and -0.075 per 0.196 octaves), such that the structure of the generated  
137 stimuli matches the correlative structure of natural sounds (5).

138           We created sequences of random correlated noise without repetitions (“no repetition”; no-  
139 rep) and sequences that contained repetitions (“repetition”; rep). In rep sequences, a certain 200-ms

140 segment occurred in total six times throughout the sequence. Rep sequences were created by  
141 inserting a separately generated 200-ms sound pattern into the 3500-ms sequence. For half of the  
142 rep sequences within an experimental block the same repeating 200-ms pattern was used, whereas  
143 for the other half a new pattern was created for each sequence. As this procedure resulted in local  
144 disruptions in the correlative structure of the sound at pattern boundaries, we controlled for these  
145 local changes by inserting six (different) 200-ms segments into no-rep sequences. Cross-fading (using  
146 5-ms half-Hanning windows centred 2.5 ms relative to the beginning and -2.5 ms relative to the end  
147 of an inserted 200-ms patterns) was used to avoid audible artefacts due to abrupt changes in the  
148 spectrum at segment boundaries. In all sequences, the time point of the first pattern onset was  
149 selected randomly between 50 and 500 ms relative to sound onset. The following pattern onsets  
150 occurred either with a constant interval of 300 ms (regular) or variable intervals between 50 and 550  
151 ms (jittered) between patterns. In jittered sequences, intervals between patterns were chosen  
152 randomly, with the restriction that the duration of two consecutive inter-pattern intervals must  
153 differ by at least 50 ms. Stimulus sequences are illustrated in Fig 1 (panel A), and audio examples can  
154 be found in the online supplemental material  
155 ([https://osf.io/xn9t4/?view\\_only=582f31e68ff646afacfb0f4135f8bd83](https://osf.io/xn9t4/?view_only=582f31e68ff646afacfb0f4135f8bd83)).

156

157 **Fig 1. Illustration of the study design.** A: Illustration of regular and jittered acoustic stimulus  
158 sequences with and without pattern repetitions. B: Experimental design. Participants took part in  
159 two EEG sessions. In the first session, their attention was directed away from the auditory  
160 stimulation, and in the second session, they were instructed to focus on repetitions in the sounds.  
161 Both sessions consisted of ten blocks in a random order, each of which contained 30 trials.

162

## 163 Procedure

164 Participants completed two EEG sessions on separate days (with on average 13 days in  
165 between). In the first session, listeners' attention was directed away from the auditory sequences

166 (no-attention), which they were instructed to ignore while performing a visual distractor task that  
167 required continuous monitoring of the visual stimulation. In the second session, their attention was  
168 directed towards the auditory sequences (attention) by a repetition detection task, which required  
169 them to indicate in each trial whether the sequence contained a repetition. The fixed session order  
170 served to avoid active knowledge about the repetitions in the auditory sequences during the no-  
171 attention session after participants performed the auditory repetition detection task in the session  
172 before. In each session, they completed five blocks with regular and five blocks with jittered  
173 sequences in a random order, with breaks between blocks as required. Each block consisted of 60  
174 randomly ordered auditory sequences, 50 % of which were rep and no-rep sequences, respectively.  
175 In 50 % of the rep sequences per block, the repeating pattern was the same across trials within the  
176 block, whereas the remaining rep sequences contained a repeating pattern that occurred in only one  
177 trial throughout the experiment. Between two consecutive sequences, silent intervals ranged  
178 between 2175 and 2625 ms in duration (in steps of 50 ms). The experimental design is illustrated in  
179 Fig 1 (panel B).

180         The visual display in the no-attention session consisted of eight squared dark-grey frames  
181 (width/height: 0.50° visual angle) arranged in a circle (radius: 2.11° visual angle) on a grey  
182 background at equal distance from a white fixation cross. In each of the 240 visual trials per block, a  
183 white square appeared at one of the eight frame positions for 150 ms. Participants were asked to  
184 fixate the cross in the centre of the screen and press a button as quickly as possible whenever the  
185 white square appeared at the same frame position as two trials before. The first five trials of each  
186 block were always non-targets, and 2-back targets occurred randomly in 10 % of the trials, each of  
187 which was followed by at least two non-targets. While square positions were chosen randomly for  
188 non-target trials, targets occurred equally often at each position. The visual stimulus onset  
189 asynchrony ranged between 1425 and 1575 ms (in steps of 10 ms), and visual stimulation had no  
190 temporal relationship with the auditory stimulation. Auditory stimulation began five seconds after  
191 the visual stimulation at the beginning of each block. At the beginning of the session, participants

192 completed a short training block without concurrent auditory stimulation, during which they  
193 received feedback about the correctness of their response in each trial. During the actual  
194 experiment, feedback (hit/false alarm rates and mean reaction time) was provided only at the end of  
195 a block.

196 At the beginning of the attention session, the different types of auditory sequences were  
197 introduced to the participants. An example sequence (which was not used during the actual  
198 experiment) was provided for sequences with “regular repetitions” (rep, regular), “irregular  
199 repetitions” (rep, jittered) or “no repetitions” (no-rep) and could be repeated as often as listeners  
200 wanted. They were informed that repetitions occurred in 50 % of the trials and that regular and  
201 irregular sequences occurred in separate blocks. A white fixation cross on a grey background was  
202 displayed during sound presentation, followed by the response options (“repetition”/“no  
203 repetition”) during the response interval (until a response was given or a maximum of 2000 ms  
204 expired). Participants pressed either the left or the right button (counterbalanced across  
205 participants) on a response time box with their left or right index finger, respectively. Feedback  
206 (percentage of correct responses) was again provided at the end of a block.

207 Participants were seated inside an acoustically and electrically shielded chamber during the  
208 experiment. Task instructions and visual stimuli were presented on a computer screen located at  
209 approximately 80 cm distance from the participants’ eyes. Auditory stimuli were delivered binaurally  
210 via headphones (Sennheiser HD-25-1, Sennheiser GmbH & Co. KG, Germany). Stimulus presentation  
211 and response registration was controlled using the Psychophysics Toolbox extension (PTB-3; (35,36)  
212 in GNU Octave (version 5.2.0), and behavioural responses were recorded with a response time box  
213 (Suzhou Litong Electronic Co., China).

## 214 **EEG data acquisition**

215 We recorded the continuous EEG from 64 Ag/AgCl electrodes mounted in an elastic cap  
216 according to the extended 10-20 system. To record horizontal and vertical eye movements,  
217 additional electrodes were placed on the outer canthus of both eyes and above and below the right

218 eye. Signals were also recorded from the left (M1) and right (M2) mastoid and from an electrode  
219 placed on the tip of the nose, which served for offline referencing. Offsets of all electrodes were  
220 kept below 30  $\mu$ V. Signals were referenced to the CMS-DRL ground, amplified with a BioSemi  
221 ActiveTwo amplifier (BioSemi B.V., Amsterdam, The Netherlands), and digitised with a sampling rate  
222 of 512 Hz.

## 223 **Data analysis and statistical inference**

224 Since the focus of the current study was the perception of pattern repetitions *within* a sound  
225 (and not the effect of pattern recurrence *across* trials as in the previous study; 34), all sequences  
226 with pattern repetitions were collapsed into the same condition (rep) for the present analysis. To  
227 make sure that the repetition of patterns across sequences did not bias the current results, the  
228 analysis was repeated analogously excluding sequences that contained repetitions of patterns that  
229 reoccurred across trials. This approach yielded a virtually identical pattern of results, thus we  
230 decided to include all sequences for the sake of statistical power.

## 231 **Behavioural data**

232 Analysis of behavioural data was done in RStudio (version 4.0.2, RStudio Inc., USA).  
233 Performance in the repetition detection task in the attention session was analysed within the  
234 framework of signal detection theory (37). Trials were classified as hits when participants correctly  
235 indicated that a rep sequence contained repetitions and as false alarms when they erroneously  
236 indicated that a no-rep sequence contained repetitions. We then computed the  $d'$  sensitivity index  
237 from hit and false alarm rates separately for regular and jittered blocks, applying a log-linear  
238 transformation (38) to avoid infinite values. To statistically test whether there was a difference in  
239 repetition detection performance between regular and jittered blocks, we compared  $d'$  scores using  
240 a two-sided paired  $t$ -test, with the standard .05 alpha criterion to define statistical significance.  
241 Bayesian tests were computed, using the package “BayesFactor” (39,40), and Bayes Factors ( $BF_{10}$ )  
242 are reported in addition to the frequentist statistics.  $BF_{10} > 3$  (10) was considered moderate (strong)

243 evidence for the alternative hypothesis and  $BF_{10} < 0.33$  (0.1) was considered moderate (strong)  
244 evidence for the null hypothesis, in accordance with widely used conventions (41), and values in  
245 between were considered inconclusive.

## 246 **EEG data**

247 Offline processing of EEG data was done in Matlab (version R2022b), using the EEGLAB  
248 (version 14.1.2; 42) and FieldTrip (43) toolboxes, and statistical analysis in RStudio (version 4.0.2).

249 **Pre-processing.** Pre-processing of EEG data was done separately for each of the two sessions  
250 per participant. After re-referencing the data to the channel on the tip of the nose, noisy channels  
251 were identified if their signal variance exceeded an absolute z-score of 3.0. These channels were  
252 excluded from pre-processing and later spherically spline interpolated. The remaining data were  
253 then high-pass and low-pass filtered using Kaiser-windowed sinc finite impulse response (FIR) filters.  
254 The cut-off for the low-pass filter was 35 Hz (transition bandwidth: 5 Hz, maximum passband  
255 deviation: 0.001, filter order: 372), while high-pass filters with different cut-offs were applied for the  
256 three EEG markers that we analysed (see below). After filtering, the continuous data were epoched  
257 from -100 to 4000 relative to sequence onset. To remove physiological and technical artefacts, an  
258 independent component analysis (ICA) was used, computed on a copy of the data filtered with a 1-  
259 Hz high-pass filter (transition bandwidth: 0.5 Hz, maximum passband deviation: 0.001, filter order:  
260 3710) to improve signal-to-noise ratio for the decomposition. Before ICA decomposition, epochs  
261 with a peak-to-peak difference exceeding 750  $\mu$ V were discarded and data were down-sampled to  
262 128 Hz. ICA weights, obtained with an infomax algorithm implemented in the runica function in  
263 EEGLAB, were transferred to the dataset with the final pre-processing parameters. Classification of  
264 independent components was done automatically using the IC Label plugin (44), and all components  
265 classified as eye blinks, muscle or cardiac activity, line or channel noise were removed. Any auditory  
266 event within 500 ms before and after a button press or within 500 ms after a visual target in the no-  
267 attention session was excluded from the analysis to minimise the influence of motor and visual  
268 activity on auditory EEG responses.

269           **Sustained response: global field power (GFP).** For the analysis of sustained activity, data  
270 were high-pass filtered (during pre-processing) with a low cut-off at 0.1 Hz (transition bandwidth: 0.2  
271 Hz, maximum passband deviation: 0.001, filter order: 9274) to avoid filtering out slow potential  
272 shifts. From the pre-processed data, we extracted epochs that ranged from -100 to 3000 ms relative  
273 to the onset of the first pattern per sequence and baseline-corrected them to the 100-ms interval  
274 prior to first pattern onset. Epochs were discarded if their peak-to-peak difference exceeded 300  $\mu$ V,  
275 and the remaining epochs were re-referenced to the average of all channels. For each participant,  
276 averages were computed for rep and no-rep sequences in each of the four attention and regularity  
277 conditions. GFP at each sampling point was computed from these within-participant averages as the  
278 root mean square (RMS) of the signal across all scalp electrodes (45).

279           For statistical evaluation, mean GFP was extracted for each attention and regularity  
280 condition from a time window that ranged from 500 to 3000 ms relative to the first pattern onset,  
281 i.e., from the first pattern repetition to the end of the sequence. We used a three-way repeated-  
282 measures ANOVA (implemented in the R package “ez”) with the factors Repetition (rep, no-rep),  
283 Attention (attention, no-attention), and Regularity (regular, jittered) to test whether GFP differed  
284 between sequences with and without sequences, and whether this effect is modulated by attention  
285 and regularity. Greenhouse-Geisser correction was applied whenever Mauchly’s test indicated non-  
286 sphericity ( $p < .05$ ). A corresponding Bayesian ANOVA (46) was again computed in addition to the  
287 frequentist ANOVA. Reported  $BF_{10}$ ’s reflect the evidence for models that include the respective  
288 (main or interaction) effect relative to reduced matched models without the respective effect (in line  
289 with recent recommendations; 47). A significant main effect of Repetition would indicate that the  
290 brain successfully picked up the pattern repetitions within sound sequences, and a significant  
291 interaction of Repetition with Attention or Regularity would indicate that the repetition effect is  
292 modulated by the respective factor. To further elucidate the nature of the modulation by Attention  
293 or Regularity, significant ( $p < .05$ ) two-way interactions with Repetition were followed up using (both  
294 frequentist and Bayesian) paired  $t$ -tests. Specifically, we computed the rep vs. no-rep contrast

295 separately for the two levels of the modulating factor (Attention or Regularity), and subsequently  
296 compared the rep-minus-no-rep difference between the two levels (i.e., attention vs. no-attention,  
297 or regular vs. jittered).

298 **Event-related potential (ERP) responses to repeating pattern onsets.** For the ERP analysis,  
299 data were filtered with a 1-Hz high-pass filter (transition bandwidth: 0.5 Hz, maximum passband  
300 deviation: 0.001, filter order: 3710) in order to filter out slow potentials. Extracted epochs ranged  
301 from -100 to 500 ms relative to single pattern onsets, averaged across the second to the sixth  
302 pattern occurrence per sequence. Epochs were discarded if their peak-to-peak difference exceeded  
303 300  $\mu\text{V}$ , and no baseline correction was applied. After re-referencing to the algebraic mean of both  
304 mastoids, we computed first within-participant averages and then grand averages across  
305 participants for rep and no-rep sequences in each of the four attention and regularity conditions.

306 A non-parametric cluster-based permutation approach was used to determine time windows  
307 of interest for the statistical evaluation of mean ERP amplitudes. To identify clusters of significant  
308 differences in amplitude between rep and no-rep sequences at adjacent sampling points along both  
309 temporal and spatial dimension, we computed a cluster-based permutation test on rep vs. no-rep  
310 averages across the four attention and regularity conditions (48,49). Averaging across attention and  
311 regularity conditions before computing the cluster-based permutation test served to reduce the risk  
312 of biased analysis parameter choices (50). Both alpha level and cluster alpha were set to 0.05, and  
313 cluster-level significance probability was estimated using a Monte Carlo approximation with 1000  
314 permutations. In the time range from 0 to 500 ms relative to pattern onset, we identified two time  
315 windows of interest, the first one ranging from 0 to 160 ms and corresponding to an early positivity,  
316 and the second one ranging from 190 to 380 ms and corresponding to a subsequent negativity.

317 Mean amplitudes were extracted from these two time windows at a fronto-central cluster of  
318 nine electrodes (F1, F2, Fz, FC1, FC2, FCz, C1, C2, Cz). Statistical evaluation was done separately for  
319 the positivity and negativity, and followed the same procedures as described above for the sustained  
320 response.

321           **Inter-trial phase coherence (ITPC).** For the analysis of ITPC, data were high-pass filtered with  
322 a cut-off at 0.5 Hz (transition bandwidth: 0.5 Hz, maximum passband deviation: 0.001, filter order:  
323 3710). Pre-processed data were epoched from -200 to 800 ms relative to single pattern onsets at the  
324 second to the sixth pattern occurrence per sequence. Epochs were demeaned, and any epoch with a  
325 peak-to-peak difference that exceeded 150  $\mu$ V was discarded. Signals were averaged within the  
326 same fronto-central electrode cluster as for the ERP analysis (see above), and 1500-ms zero-padding  
327 was applied at both ends of each epoch. We then used a convolution with Morlet wavelets to  
328 extract phase information from single epochs over a frequency range from 1 to 10 Hz (in steps of 0.2  
329 Hz), with parameters of the wavelet linearly adjusted from three to seven wavelet cycles. ITPC  
330 between epochs was computed for each participant from the results of the wavelet convolution at  
331 each sampling point in the time-frequency space, separately for rep and no-rep sequences in each of  
332 the four attention and regularity conditions. We again used a cluster-based permutation approach to  
333 determine the time-frequency window of interest for statistical evaluation. After averaging across  
334 the four attention and regularity conditions, we computed a cluster-based permutation test (rep vs.  
335 no-rep), with an alpha level and cluster alpha of 0.001 (and again using a Monte Carlo approximation  
336 with 1000 permutations to estimate cluster-level significance probability). The test revealed a broad  
337 significant cluster that ranged from 0 to 500 ms relative to pattern onset and spanned a frequency  
338 range from 1 to 4 Hz.

339           We extracted mean ITPC from this time-frequency window of interest for subsequent  
340 statistical evaluation, which followed the same procedures as for the analysis of sustained response  
341 and ERPs to repeating pattern onsets.

342

## 343 **Results**

### 344 **Behavioural data**

345 Participants detected pattern repetitions in the acoustic sequences on average above  
346 chance in both regular ( $M \pm SD$  of  $d'$ :  $2.01 \pm 0.97$ ) and jittered ( $M \pm SD$  of  $d'$ :  $1.84 \pm 1.11$ ) blocks.  
347 There was no significant difference between the two ( $t(28) = 1.92$ ;  $p = .065$ ;  $d = 0.36$ ;  $BF_{10} = 0.99$ ),  
348 however Bayesian evidence was inconclusive. Thus, there might in fact be a trend towards better  
349 repetition detection performance in regular than in jittered sequences, though the effect of  
350 temporal regularity seems to be rather small.

## 351 EEG data

### 352 Sustained response: GFP

353 As displayed in Fig 2, GFP overall increased rather sharply at the beginning of a sequence  
354 before reaching a relatively sustained plateau phase throughout the rest of the sequence from  
355 around 500 ms after the first pattern onset. In regular rep sequences (across both attention  
356 conditions), we observed an additional periodic modulation of the potential during the sustained  
357 phase at the frequency of the isochronous repeating pattern onsets (i.e., 2 Hz). Any such response  
358 relative to repeating pattern onsets would be levelled out due to the random shift of pattern onsets  
359 in jittered sequences. Crucially, GFP was significantly higher in rep compared to no-rep sequences  
360 (main effect of Repetition:  $F(1, 28) = 48.39$ ,  $p < .001$ , partial  $\eta^2 = .63$ ,  $BF_{10} = 2.21 \cdot 10^5$ ), suggesting that  
361 the brain automatically picked up pattern repetitions in rep sequences. This repetition effect was  
362 modulated by attention (Repetition x Attention interaction:  $F(1, 28) = 6.80$ ,  $p = .014$ , partial  $\eta^2 = .20$ ,  
363  $BF_{10} = 0.87$ ): While there was a significant increase in GFP for rep compared to no-rep sequences  
364 during both attention ( $t(28) = 6.65$ ;  $p < .001$ ;  $d = 1.24$ ;  $BF_{10} = 5.05 \cdot 10^4$ ) and in-attention ( $t(28) = 5.55$ ;  
365  $p < .001$ ;  $d = 1.03$ ;  $BF_{10} = 3.30 \cdot 10^3$ ), the effect was larger when listeners' attention was focussed on  
366 the sounds ( $t(28) = 2.61$ ;  $p = .014$ ;  $d = 0.48$ ;  $BF_{10} = 3.34$ ). Conversely, the influence of regularity on  
367 the repetition effect was less clear (Repetition x Regularity interaction:  $F(1, 28) = 5.41$ ,  $p = .027$ ,  
368 partial  $\eta^2 = .16$ ,  $BF_{10} = 0.47$ ): The repetition effect was significant in both regular ( $t(28) = 4.67$ ;  $p <$   
369  $.001$ ;  $d = 0.87$ ;  $BF_{10} = 366.93$ ) and jittered ( $t(28) = 6.81$ ;  $p < .001$ ;  $d = 1.26$ ;  $BF_{10} = 7.41 \cdot 10^4$ ) blocks,

370 and there was a trend towards a larger effect in jittered blocks, although only with inconclusive  
371 Bayesian evidence ( $t(28) = 2.33$ ;  $p = .027$ ;  $d = 0.43$ ;  $BF_{10} = 1.96$ ).

372

373 **Fig 2. Sustained activity throughout the sequence.** Global field power (GFP) relative to the onset of  
374 the first pattern occurrence per sequence (0 ms) for rep and no-rep sequences in each of the four  
375 Attention x Regularity conditions. Bar plots display mean amplitudes in the time window of interest  
376 (500 to 3000 ms; marked by the light-grey box). Shaded areas and error bars indicate  $\pm 1$  SEM.

377

### 378 **ERPs to repeating pattern onsets**

379 ERPs to the onsets of the repeating pattern within a sequence are shown in Fig 3. Repeating  
380 pattern onsets in rep sequences elicited an early positivity, followed by a later negativity from  
381 around 200 ms relative to pattern onset, both with a fronto-central topography, whereas no such  
382 ERP modulation occurred for no-rep sequences. This pattern-related positivity-negativity complex  
383 was elicited consistently across all attention and regularity conditions, with differences only in the  
384 latency of the positivity: While the onset of the positivity was around pattern onset in jittered  
385 sequences, it was shifted forwards in regular sequences, likely related to anticipation of upcoming  
386 pattern repetitions in temporally regular and predictable sequences. For both positivity (0-160 ms)  
387 and negativity (190-380 ms) effects of Repetition, Attention and Regularity pointed into the same  
388 directions: Mean amplitudes were larger (i.e., more positive or negative, respectively) in rep than in  
389 no-rep sequences (main effect of Repetition: positivity:  $F(1, 28) = 123.29$ ,  $p < .001$ , partial  $\eta^2 = .81$ ,  
390  $BF_{10} = 8.30 \times 10^{47}$ ; negativity:  $F(1, 28) = 182.74$ ,  $p < .001$ , partial  $\eta^2 = .87$ ,  $BF_{10} = 2.91 \times 10^{55}$ ). While the  
391 repetition effect was not significantly modulated by regularity (Repetition x Regularity interaction:  
392 positivity:  $F(1, 28) = 0.21$ ,  $p = .654$ , partial  $\eta^2 = .01$ ,  $BF_{10} = 0.32$ ; negativity:  $F(1, 28) = 1.57$ ,  $p = .220$ ,  
393 partial  $\eta^2 = .05$ ,  $BF_{10} = 0.27$ ), there was a substantial influence of attention (Repetition x Attention  
394 interaction: positivity:  $F(1, 28) = 25.99$ ,  $p < .001$ , partial  $\eta^2 = .48$ ,  $BF_{10} = 1.49 \times 10^3$ ; negativity:  $F(1, 28) =$   
395  $52.98$ ,  $p < .001$ , partial  $\eta^2 = .65$ ,  $BF_{10} = 4.46 \times 10^7$ ): Amplitudes differed significantly between rep and

396 no-rep sequences during both attention (positivity:  $t(28) = 12.57$ ;  $p < .001$ ;  $d = 2.33$ ;  $BF_{10} = 1.54 \cdot 10^9$ ;  
397 negativity:  $t(28) = 13.88$ ;  $p < .001$ ;  $d = 2.58$ ;  $BF_{10} = 1.53 \cdot 10^{11}$ ) and in-attention (positivity:  $t(28) = 7.71$ ;  
398  $p < .001$ ;  $d = 1.43$ ;  $BF_{10} = 6.39 \cdot 10^5$ ; negativity:  $t(28) = 9.70$ ;  $p < .001$ ;  $d = 1.80$ ;  $BF_{10} = 5.48 \cdot 10^7$ ), but an  
399 attentional focus on the auditory sequences increased this repetition effect (positivity:  $t(28) = 5.10$ ;  
400  $p < .001$ ;  $d = 0.95$ ;  $BF_{10} = 1.07 \cdot 10^3$ ; negativity:  $t(28) = 7.28$ ;  $p < .001$ ;  $d = 1.35$ ;  $BF_{10} = 2.30 \cdot 10^5$ ).

401

402 **Fig 3. Event-related responses to repeating pattern onsets.** Event-related potentials (ERPs) relative  
403 to the onset of repeating patterns at position 2 to 6 within the sequence (0 ms) for rep and no-rep  
404 sequences in each of the four Attention x Regularity conditions. Bar plots display mean amplitudes in  
405 the time windows of interest (early positivity: 0 to 160 ms; later negativity: 190 to 380 ms; marked  
406 by light-grey boxes) at a fronto-central electrode cluster. Topographies show the rep-minus-no-rep  
407 difference potential in the respective time window of interest. Shaded areas and error bars indicate  
408  $\pm 1$  SEM.

409

## 410 ITPC

411 As shown in Fig 4, pattern repetitions within a sound sequence led to an increase in ITPC of  
412 neural oscillations (compared to no-rep sequences). ITPC was strongest around the onsets of the  
413 repeating pattern for low frequencies around the rates of pattern occurrence in the stimulation. In  
414 regular sequences, the ITPC peak appeared more focal along the frequency dimension, which  
415 reflects the strict 2-Hz periodicity in the stimulation compared to jittered sequences that comprise a  
416 broader range of frequencies (1.33 to 4 Hz). Statistical evaluation of mean ITPC between 0 and 500  
417 ms relative to pattern onset showed that phase coherence of 1-4 Hz oscillations was overall stronger  
418 in rep than in no-rep sequences (main effect of Repetition:  $F(1, 28) = 69.61$ ,  $p < .001$ , partial  $\eta^2 = .71$ ,  
419  $BF_{10} = 8.91 \cdot 10^{23}$ ). The repetition effect was significantly modulated by attention (Repetition x  
420 Attention interaction:  $F(1, 28) = 63.35$ ,  $p < .001$ , partial  $\eta^2 = .69$ ,  $BF_{10} = 5.12 \cdot 10^9$ ): The increase in  
421 ITPC for rep compared to no-rep sequences was significant during both attention ( $t(28) = 9.25$ ;  $p <$

422 .001;  $d = 1.72$ ;  $BF_{10} = 2.09 \cdot 10^7$ ) and in-attention ( $t(28) = 4.37$ ;  $p < .001$ ;  $d = 0.81$ ;  $BF_{10} = 178.13$ ), but  
423 the difference was substantially larger during attention ( $t(28) = 7.96$ ;  $p < .001$ ;  $d = 1.48$ ;  $BF_{10} =$   
424  $1.14 \cdot 10^6$ ). Similarly, regularity also influenced the magnitude of the repetition effect (Repetition x  
425 Regularity interaction:  $F(1, 28) = 7.03$ ,  $p = .013$ , partial  $\eta^2 = .20$ ,  $BF_{10} = 2.09$ ): While there was a  
426 significant repetition effect in both regular ( $t(28) = 7.57$ ;  $p < .001$ ;  $d = 1.41$ ;  $BF_{10} = 4.56 \cdot 10^5$ ) and  
427 jittered ( $t(28) = 7.55$ ;  $p < .001$ ;  $d = 1.40$ ;  $BF_{10} = 4.35 \cdot 10^5$ ) blocks, the effect was larger in regular  
428 blocks ( $t(28) = 2.65$ ;  $p = .013$ ;  $d = 0.49$ ;  $BF_{10} = 3.65$ ).

429

430 **Fig 4. Phase coherence of neural oscillations.** Inter-trial phase coherence (ITPC) over frequencies  
431 and time relative to the onset of repeating patterns at position 2 to 6 within the sequence (0 ms) at  
432 a fronto-central electrode cluster for rep and no-rep sequences in each of the four Attention x  
433 Regularity conditions. Bar plots display mean ITPC between 1 and 4 Hz in a time window from 0 to  
434 500 ms relative to pattern onset (marked by dotted lines). Error bars indicate  $\pm 1$  SEM.

435

436

## 437 Discussion

438 The current study set out to test whether and how listeners' attention and the temporal  
439 regularity of pattern occurrence within a continuous sound sequence modulate pattern repetition  
440 perception. We presented listeners with sequences of correlated noise that contained or did not  
441 contain repetitions of a certain sound segment. Pattern repetitions within a sequence were either  
442 temporally regular or jittered, and listeners' attention was either directed towards or away from the  
443 sounds during stimulus presentation. Besides behavioural repetition detection (when participants  
444 attended to the sounds), we measured repetition perception and its modulation by attention and  
445 regularity by means of three different EEG signatures: sustained activity throughout the full  
446 sequence (from repetition onset), ERPs and ITPC time-locked to repeating pattern onsets.

447 Overall, listeners were able to behaviourally detect repetitions well above chance (when  
448 they attended to the sounds), and successful repetition detection was reflected consistently in all  
449 three neural markers across attention and regularity conditions. Concretely, repetitions of a specific  
450 pattern within a continuous acoustic stimulus led to an increase in sustained activity from the first  
451 pattern repetition through the end of the sequence (for consistent previous results, see:  
452 22,24,25,27–29), a characteristic positivity-negativity complex in the ERP time-locked to repeating  
453 pattern onsets (15,16,18,20,26,33), and enhanced ITPC of low-frequency (1-4 Hz) oscillations  
454 (15,16,19,20,25). Notably, besides replicating findings of different earlier studies all within the same  
455 dataset, we could demonstrate automatic detection of irregular, unpredictable pattern repetitions  
456 while listeners focussed on a demanding visual distractor task. Thus, we show that not only strict  
457 periodicities (15,16,22,25,27–29,33), but also more irregular pattern repetitions within continuous  
458 auditory input are processed pre-attentively. This suggests that repetition detection does not rely on  
459 a merely temporal mechanism (i.e., the detection of an autocorrelation with a fixed time lag in the  
460 acoustic signal), but on a continuous comparison between the current input and a sensory  
461 representation of a recently presented sound segment.

462 While pattern repetitions were detected automatically in both regular and jittered  
463 sequences during both attention and in-attention, repetition perception was substantially  
464 modulated by both factors. Our two-by-two within-subject design allowed to directly compare  
465 different levels of attention and regularity, and to show that an attentional focus onto the sounds  
466 substantially enhanced repetition perception. The repetition effect (i.e., the difference between  
467 sequences with and without pattern repetitions) was larger during attention than during in-attention  
468 to the auditory stimulation across all three neural markers. In contrast, earlier studies had suggested  
469 rather comparable magnitudes of the repetition effect between attention and no-attention as  
470 reflected in sustained activity (27), ERPs (15,16,33), and ITPC (25). However, most of these studies  
471 did either not compare attention conditions directly (15,16,22), used a between-subject design (27),  
472 or controlled attention less strictly (33). We argue that attention to the stimulus sequences (and, in

473 particular, potential repetitions therein) enhances perceptual representation of the sound and  
474 thereby facilitates repetition detection. Sharpened short-term representations of the repeating  
475 pattern through attention may in turn boost robust memory formation for specific patterns that  
476 recur across multiple trials at a longer time scale (and potentially higher level of abstraction), which  
477 has been demonstrated previously (8,13–17,21,23,24,30–32).

478         Conversely, the influence of temporal regularity on repetition perception appeared  
479 somewhat less clear and consistent across different neural markers: While there was no difference  
480 in amplitude and morphology of the ERP to repeating pattern onsets between regular and jittered  
481 sequences, the repetition effect tended to be smaller for regular sequences in terms of sustained  
482 activity, but larger in terms of ITPC. The absence of a regularity-related difference in the ERP effect is  
483 only partly in agreement with the results of a previous study by Hodapp & Grimm (2021), who  
484 reported no difference in amplitude of the negative ERP component between regular and jittered  
485 pattern repetitions, whereas the early positive ERP component exclusively occurred in the regular  
486 condition. By contrast, the occurrence of both components across regular and jittered sequences in  
487 our data suggests that positivity and negativity do not subserve different functions (e.g., tracking of  
488 stimulus periodicity vs. detection of repeating pattern onsets), but rather that the positivity-  
489 negativity complex as a whole is related to pattern repetition detection. Nevertheless, the  
490 (descriptive) forward shift of the onset of the positivity for regular (compared to jittered) pattern  
491 onsets may indicate that anticipation of upcoming pattern occurrences in predictable sequences is  
492 reflected in the latency (but not in the magnitude) of the ERP response. If anticipation of upcoming  
493 pattern onsets indeed modulates the time course of the ERP such that the early positivity reaches  
494 into a time window before actual pattern onset, baseline correction could introduce amplitude  
495 differences between regular and irregular sequences by differentially shifting the whole positivity-  
496 negativity complex into a negative or positive direction (which may also explain discrepancies with  
497 regard to the presence of the early positivity in earlier studies, e.g., 15,26). A similar interpretation  
498 may hold for the stronger ITPC effect we observed for regular than for jittered sequences: The strict

499 periodicity in the stimulation allowed for (additional) entrainment of brain responses to the stimulus  
500 rhythm and for temporal prediction of the next pattern onset, which was not possible in  
501 unpredictable jittered sequences. Importantly, the presence of a significant repetition-related ITPC  
502 increase for jittered sequences suggests that the phase alignment of EEG responses cannot be  
503 explained merely by entrainment to the stimulus periodicity. Instead, synchronisation of neural  
504 responses relative to repeating pattern onsets occurred irrespective of their temporal regularity,  
505 possibly achieved via phase-reset of ongoing oscillations (19,51). Finally, there was a trend towards a  
506 larger repetition effect in sustained activity for jittered compared to regular sequences, which may  
507 seem counterintuitive at first glance. Especially in the attention condition, this effect seems to be  
508 driven by a GFP difference between regular and jittered sequences without pattern repetitions,  
509 whereas mean GFP was (descriptively) fairly similar for sequences with repetition. This suggests that  
510 there might have been rudimentary processing of local disruptions in the correlative structure of the  
511 stimulus sequences when they occurred strictly periodically (but not when their occurrence was  
512 jittered and unpredictable), which in turn decreased the difference between rep and no-rep  
513 sequences (i.e., the repetition effect).

514         Unlike Herrmann & Johnsrude (2018), we did not find evidence for a distinct pattern of  
515 attention modulation between sustained activity and phase coherence of neural oscillations. If  
516 anything, our data provide more evidence for an attention modulation of the repetition effect in  
517 ITPC than in GFP, whereas Herrmann & Johnsrude (2018) reported an attention effect only for  
518 sustained activity, but not for ITPC (i.e., neural synchronisation). They proposed that the distinct  
519 susceptibility of sustained activity and neural synchronisation to the influence of attention may  
520 indicate that the two neural markers reflect dissociable processes, such that neural synchronisation  
521 is related to an early attention-independent sensory process and sustained activity to a more  
522 abstract representation of structure in sounds that requires attention (25). While this does not  
523 preclude that different EEG markers reflect functionally nuanced processes that contribute to  
524 (automatic) repetition perception, our data suggest that all of them underlie a similar modulatory

525 influence by attention. Different weighting of putative subprocesses and their susceptibility to  
526 attention (and possibly regularity) modulation might rather arouse from subtle differences in the  
527 experimentally created listening context (e.g., specific stimulus material and distractor task).

528           In summary, our study replicates the results of earlier studies that showed rapid and  
529 automatic detection of pattern repetitions within continuous acoustic sequences. Crucially, pattern  
530 repetitions are processed pre-attentively even if there is no temporal regularity that could act as a  
531 cue for upcoming (predictable) pattern occurrences. This suggests that repetition perception relies  
532 on a mechanism that flexibly adapts to varying contextual demands, such as they occur in  
533 naturalistic listening situations. Yet, an attentional focus on the auditory input enhances sensory  
534 representation of repeating patterns and facilitates repetition detection.
