# 1 Supporting Materials

# 2 Text 1. Existing ML-based wetland CH<sub>4</sub> upscaling products

(Peltola et al., 2019) upscaled monthly CH<sub>4</sub> fluxes for the Arctic-boreal freshwater wetland in
 2013-3014 at 0.25°-0.5° spatial resolution with three temporal variables including MODIS LST at
 night, snow cover, and potential radiation, as well as a static binary permafrost map. The
 training data composed 488 monthly data records from 25 EC tower sites, spanning 2005-2016.

- 8 (McNicol et al., 2023) upscaled monthly CH<sub>4</sub> fluxes for global freshwater wetland in 2001-2018
- 9 at 0.25° with air temperature (with and without a 2-week lag), MODIS EVI with a 3-week lag,
- 10 mean temperature of the driest quarter, precipitation of the wettest month, and vegetation
- 11 canopy height (Simard et al., 2011). Meteorological data was from WorldClim (Fick & Hijmans,
- 12 2017). The training data consisted of 6,210 weekly observations between 2006 and 2018
- 13 acquired from 43 EC sites.
- 14

## 15 Text 2. Tower EC flux data

16 The base of our EC data collection stems from a publicly available global synthesis coordination of FLUXNET-CH<sub>4</sub>, which includes 79 EC tower sites (42 are freshwater wetland sites) and 293 17 site-years of data. We collected both daily and half-hourly data from 44 sites in the Arctic-boreal 18 19 region (>45° N), accounting for 167 site years as our base dataset, to which we added data 20 from 6 new sites (31 site-years) and added additional data to 9 existing sites (21 site-years) 21 contributed by site PIs (Table S2). In total, we assembled data from 50 EC tower sites in northern latitudes (219 site-years), of which 33 are from wetlands (155 site-years), with 13 wet 22 23 tundra sites, 11 fens, and 9 bogs. Data entries with missing data in gridded predictors were 24 excluded, including 5 wetland sites (FI-LOM, DE-SFN, RU-SAM, RU-VRK, SE-ST1) where data 25 was collected before SMAP data was available. Another 2 sites (CA-BOU, RU-COK) were 26 excluded after quality control. After quality filtering, data from 26 wetland sites were used for 27 analysis (Table S2).

28

29 Half-hourly data obtained from FLUXNET-CH<sub>4</sub> were gap-filled following the FLUXNET protocols

- 30 (Pastorello et al., 2020). Specifically, for CH<sub>4</sub> fluxes (FCH<sub>4</sub>), the FLUXNET-CH<sub>4</sub> gap-filling
- 31 procedure includes filling gaps in meteorological variables with ERA-Interim reanalysis data and
- 32 then gap-filling FCH<sub>4</sub> using artificial neural networks (ANN) (Knox et al., 2019). Variables used to
- 33 gap-fill FCH<sub>4</sub> included air temperature (TA), downward-incoming shortwave radiation (SWin),
- 34 wind speed (WS), air pressure (PA), and sine and cosine functions to represent seasonality. For
- the sites with additional half-hourly data that we assembled in this study, we used the same
- 36 predictors to fill gaps in FCH<sub>4</sub> except for gap-filling meteorological variables with ERA5 data. We
- used RF algorithm as it can fill gaps within 12 days with low normalized MAE for fens and bogs (labor table 2021). The  $P_{2}^{2}$  of the second days with low normalized MAE for fens and bogs
- 38 (Irvin et al., 2021). The  $R^2$  of gap-filling models across sites ranged 0.35-0.89 (mean  $R^2$  = 0.68).

- 39 The 33 wetland sites accounted for 74% of the daily EC tower data after quality control. The
- 40 remaining 26% data consisted of 17 non-wetland sites, including upland forests, meadows, dry
- 41 tundra, pasture, and lakes (Table S2).

# 42 Text 3. Bottom-up and top-down models

43 The bottom-up estimates we used for comparison were from sixteen wetland CH<sub>4</sub> models in the 44 Global Carbon Project (GCP) Methane Budget (Z. Zhang et al., 2023). We calculated the mean 45 annual and mean seasonal emissions and uncertainties for the study area from the model 46 diagnostic simulations using a gridded climate data set from Climate Research Unit (CRU) as 47 the inputs. The maximum and minimum estimations in each year were identified as the upper 48 and lower bounds of the uncertainty range. Mean annual and mean seasonal emissions were 49 also calculated from 18 extensive WetCHARTs models, with the maximum and minimum values 50 representing the range of uncertainties. 51

52 The top-down inversions were from the atmospheric methane assimilation system,

53 CarbonTracker-CH<sub>4</sub>, which can simulate monthly CH<sub>4</sub> emitted to the atmosphere attributed to

54 microbial, fossil, and pyrogenic sources at 2° x 3° resolution (Bruhwiler et al., 2014). In the high

55 latitudes, microbial emissions mainly consist of natural wetland and open water emissions, and

- 56 ruminant and wild animal emissions.
- 57

# 58 Text 4. ML algorithms comparison

59

60 Many studies have endorsed random forest as outperforming other machine learning algorithms in gap-filling and upscaling CH<sub>4</sub> fluxes (Irvin et al., 2021; Kim et al., 2020; C. Zhang et al., 2020). 61 62 We tested ANN and SVM with the same dataset we used to build the ensemble random forest 63 models. Results indicate that random forest models outperformed ANN and SVM in these 64 wetlands with higher R<sup>2</sup> and lower MAE and RMSE (Fig. S8). The ability of random forest to 65 handle highly nonlinear problems supports upscaling the temporally highly varied and spatially 66 heterogeneous CH<sub>4</sub> fluxes. Random forest can incorporate continuous, discontinuous, and categorical variables. Properly tuned random forest models can avoid overfitting and may 67 capture nonlinear and discontinuous signals in environmental variables (Kim et al., 2020), such 68 as soil moisture, to better model daily variability in CH<sub>4</sub> fluxes. 69 70

# 71 Text 5. Model predictive performance at sites

72 We examined 9 EC sites where model predictive performance was below median performance

73 metrics (1 bog, 2 fen, and 6 wet tundra sites). The R<sup>2</sup> between the upscaled fluxes and

74 observations at a fen site (US-BZF) and 3 wet tundra sites (RU-CHE, US-ATQ, US-BEO) were

- significantly improved compared to the predictive performance at these sites when they were
- 76 taken out of training, indicating the unique patterns in these sites. Drainage is observed in US-

77 BZF and RU-CHE (Kwon et al., 2022). JJA and SON season fluxes at CA-PB1, US-ATQ, US-

NGC sites were overestimated, where US-ATQ contains sandy soils (Wang et al., 2022) and

CA-PB1 is drier compared to a sedge-dominated peatland site CA-PB2 (Humphreys et al.,2021).

81

82 RU-CHE and RU-CH2 are two Chersky sites in East Siberian Russia about 600m apart from 83 each other to form a paired disturbance experiment. RU-CH2 is a control tower over an 84 undisturbed wetland, whereas RU-CHE is a tower affected by artificial drainage. The above-85 around conditions of the two sites are virtually identical, but soil temperature and moisture are 86 different. Drainage caused lower CH<sub>4</sub> fluxes at RU-CHE compared to those at RU-CH2 (Fig. 87 S7). However, the grid-level input could not discern the soil conditions at both sites due to 88 coarser spatial resolution, resulting in low model predictive performance at the RU-CHE site. 89 90 US-Los is a small wetland where previous work has shown that water-table depth and 91 shortwave radiation covary and are good predictors of methane fluxes (Burdun et al., 2023). 92 Half-hourly air temperature is also correlated with diurnal methane fluxes, with some component 93 of methanogenesis likely transported via lateral aquatic fluxes (Reed et al., 2018). The wetland

94 is associated with the presence of glacial till affecting its elevation, and thus elevation is found to

95 be a good predictor of methane emissions at local scales.

<sup>\*</sup>GIEMS2 represents the minimum extents of northern wetlands.

244 \*\*GLWD provides a representation of the maximum extent of northern wetlands.

245 \*\*\*These numbers are derived from CT natural microbial emissions, which include emissions from wetlands, river/lake/pond systems,

and possibly wild animals (despite the small amount).
