## **ABSTRACT**

The Large Magellanic Cloud (LMC) presents a unique environment for pulsar population studies due to its distinct star formation characteristics and proximity to the Milky Way. As part of the TRAPUM (TRAnsients and PUlsars with MeerKAT) Large Survey Project, we are using the core array of the MeerKAT radio telescope (MeerKAT) to conduct a targeted search of the LMC for radio pulsars at L-band frequencies, 856–1712 MHz. The excellent sensitivity of MeerKAT, coupled with a 2-hour integration time, makes the survey 3 times more sensitive than previous LMC radio pulsar surveys. We report the results from the initial four survey pointings which has resulted in the discovery of seven new radio pulsars, increasing the LMC radio pulsar population by 30 per cent. The pulse periods of these new pulsars range from 278 to 1690 ms, and the highest dispersion measure is 254.20 pc cm<sup>-3</sup>. We searched for, but did not find any significant pulsed radio emission in a beam centred on the SN 1987A remnant, establishing an upper limit of 6.3 μJy on its minimum flux density at 1400 MHz.

**Key words:** pulsars: general – galaxies: Magellanic Clouds – pulsars: individual: PSR J0509–6838, PSR J0509–6845, PSR J0518–6939, PSR J0518–6946, PSR J0519–6931, PSR J0534–6905

## <span id="page-0-0"></span>**1 INTRODUCTION**

The Large Magellanic Cloud (LMC) and the Small Magellanic Cloud (SMC) are two irregular galaxies and the closest galactic companions to the Milky Way. As a result, the Magellanic Clouds have been an enduring reference for drawing parallels and contrasts with our Galaxy. They offer an ideal setting for the study of stellar populations and how their environments impact the process of star formation. Situated beyond the boundaries of the disc of the Milky Way at a distance of 49.6 kpc [\(Graczyk et al.](#page-10-0) [2020\)](#page-10-0), the LMC benefits from a particularly advantageous observational angle, notably from the Southern Hemisphere, with a lower line-of-sight dust extinction in comparison to our own Galaxy.

The SMC has a low average metallicity of [Fe/H] =  $(-0.97 \pm 1.000)$ 0.05) dex [\(Choudhury et al.](#page-10-1) [2020\)](#page-10-1), implying that it will have a distinct stellar environment with less massive stars being formed [\(Pak](#page-10-2)[mor et al.](#page-10-2) [2022\)](#page-10-2). In contrast, the LMC has a similar mean stellar metallicity,  $[Fe/H] = (-0.42 \pm 0.04)$  dex [\(Choudhury et al.](#page-10-3) [2021\)](#page-10-3), to that of the thin disc of the Milky Way,  $[Fe/H] = -0.5$  dex [\(Mat](#page-10-4)[teucci](#page-10-4) [2014\)](#page-10-4), which allows us to compare the star formation histories between the two galaxies. The LMC has a greater abundance of supernova remnants (SNRs, [Badenes et al.](#page-9-1) [2010;](#page-9-1) [Zangrandi et al.](#page-11-0) [2024\)](#page-11-0) and high-mass X-ray binaries (HMXBs, [Liu et al.](#page-10-5) [2005;](#page-10-5) [Antoniou](#page-9-2) [& Zezas](#page-9-2) [2016\)](#page-9-2) per unit mass than our Galaxy, giving an indication of the high star formation rate prevailing there [\(Grimm et al.](#page-10-6) [2003\)](#page-10-6). Consequently, it is anticipated that a larger proportionate population of isolated young neutron stars (hereafter NSs) and NSs in binary systems, especially with massive star companions, will be found within the LMC. Young pulsars, generally rotation-powered, are often associated with SNRs, and they tend to have irregular rotation patterns which are attributed to 'glitches' and timing noise (e.g. [Lyne](#page-10-7) [1999;](#page-10-7) [Haskell & Melatos](#page-10-8) [2015;](#page-10-8) [Basu et al.](#page-9-3) [2022\)](#page-9-3). Accretion-powered

<sup>★</sup> E-mail: [venuprayag@gmail.com](mailto:venu.prayag@gmail.com)

pulsars, such as the progenitors to millisecond pulsars (MSPs), are found in binaries. The transfer of angular momentum during the accretion phase of binaries leads to MSPs having pulse periods typically shorter than 10 ms [\(Alpar et al.](#page-9-4) [1982;](#page-9-4) [Radhakrishnan & Srinivasan](#page-10-9) [1982;](#page-10-9) [Papitto et al.](#page-10-10) [2013\)](#page-10-10).

The present pulsar population of the LMC consists of 25 pulsars, while the SMC is home to 16 pulsars [\(Manchester et al.](#page-10-11)  $2005$ )<sup>[1](#page-1-0)</sup>. Out of these, 14 from the SMC (see [Carli et al.](#page-9-5) [2024\)](#page-9-5) and 24 from the LMC have been detected in the radio domain. Together, these 38 pulsars constitute the extragalactic rotation-powered radio pulsar population, which accounts for only about 1 per cent of the more than 3500 radio pulsars discovered to date.

Currently, there is only one known extragalactic binary pulsar system, PSR J0045–7319, located in the SMC [\(McConnell et al.](#page-10-12) [1991;](#page-10-12) [Kaspi et al.](#page-10-13) [1994\)](#page-10-13). The potential discovery of binary systems in the LMC, particularly double NS systems, could provide valuable insights into the extragalactic NS population and the rate of extragalactic NS mergers. In addition, recent evidence for the gravitational wave background using pulsar timing arrays [\(Agazie et al.](#page-9-6) [2023;](#page-9-6) [EPTA Collaboration et al.](#page-10-14) [2023;](#page-10-14) [Reardon et al.](#page-10-15) [2023;](#page-10-15) [Xu et al.](#page-11-1) [2023\)](#page-11-1) highlights the significance of discovering stable extragalactic MSPs. Pulsars located closely together in the sky exhibit a significantly greater timing correlation due to the gravitational wave Earth-term, compared to pulsars with greater spatial separations. So far, there have been no MSPs found in the Magellanic Clouds.

Pulsars within the LMC provide a unique line-of-sight that passes through the interstellar medium (ISM) of the LMC and that of the Milky Way, as well as the intergalactic medium. As pulsar signals propagate through these regions, they interact with electrons, causing dispersion that follows a quadratic dependence on radio frequency. This is quantified as the dispersion measure (DM), which depends on the total electron column density between Earth and the pulsar. By finding a large number of radio pulsars in different locations of the LMC, we can probe the different regions, enhancing our understanding of their electron density content.

One telescope which has the required sensitivity and optimal geographical location to efficiently observe the LMC is the Parkes 64 m radio telescope, recently given the indigenous Wiradjuri name "Murriyang" (hereafter Murriyang), located in New South Wales, Australia. Murriyang has played, and continues to play, an instrumental role in the search for pulsars, having discovered 22 out of the 25 known pulsars in the LMC [\(McCulloch et al.](#page-10-16) [1983;](#page-10-16) [McConnell](#page-10-12) [et al.](#page-10-12) [1991;](#page-10-12) [Crawford et al.](#page-10-17) [2001;](#page-10-17) [Manchester et al.](#page-10-18) [2006;](#page-10-18) [Ridley et al.](#page-10-19) [2013;](#page-10-19) [Hisano et al.](#page-10-20) [2022\)](#page-10-20).

MeerKAT [\(Jonas & MeerKAT Team](#page-10-21) [2016;](#page-10-21) [Camilo et al.](#page-9-7) [2018\)](#page-9-7), located in the Karoo in the Northern Cape province of South Africa at a latitude of –30°43′ [\(Bailes et al.](#page-9-8) [2020\)](#page-9-8), is a state-of-the-art radio telescope also well placed to observe the LMC. Transients and Pulsars with MeerKAT<sup>[2](#page-1-1)</sup> (TRAPUM) is a large survey project with the aim to search for new pulsars, as well as various transient phenomena at radio frequencies [\(Stappers & Kramer](#page-10-22) [2016\)](#page-10-22). One of the objectives of TRAPUM is to survey the Magellanic Clouds and here, we report the results from the first four pointings of the TRAPUM LMC Survey.

Our paper is structured as follows: in [Section 2,](#page-1-2) we review previous surveys of the LMC and examine the current LMC pulsar population. We describe our approach to source selection and the planning of observations in [Section 3.](#page-1-3) In [Section 4,](#page-4-0) we outline the observation setup and the search process. We present the results obtained from the initial four pointings of the survey in [Section 5.](#page-6-0) Finally, in [Section 6,](#page-8-0) we conclude on our findings.

## <span id="page-1-2"></span>**2 PREVIOUS SURVEYS AND DISCOVERIES**

The first discovery of a pulsar in the LMC, PSR J0529–6652, and in fact the first extragalactic radio pulsar discovery, was made by [McCulloch et al.](#page-10-16) [\(1983\)](#page-10-16). The discovery was part of a survey of the Magellanic Clouds using Murriyang, undertaken between 1980 and 1987, that was eventually improved and extended by [McConnell](#page-10-12) [et al.](#page-10-12) [\(1991\)](#page-10-12), yielding two more pulsars in the LMC. The observations lasted 5000 s each, with the most common observation parameters being a centre frequency of 610 MHz and a total bandwidth of 60 MHz spread across 24 channels. The implementation of the Murriyang multibeam receiver [\(Staveley-Smith et al.](#page-10-23) [1996\)](#page-10-23) paved the way for higher sensitivity surveys such as the Parkes Multibeam Pulsar Survey (PMPS), which focused on the Galactic plane [\(Manchester et al.](#page-10-24) [2001\)](#page-10-24), conducted between 2000 and 2001. Around the same time, using the Murriyang multibeam receiver, [Manchester et al.](#page-10-18) [\(2006\)](#page-10-18) searched for radio pulsars in the Magellanic Clouds. The most recent, and still ongoing, LMC survey using Murriyang, initiated in the year 2009, is known as the High Resolution LMC Survey [\(Ridley et al.](#page-10-19) [2013;](#page-10-19) [Hisano et al.](#page-10-20) [2022\)](#page-10-20).

[Manchester et al.](#page-10-18) [\(2006\)](#page-10-18) observed the LMC using a total of 136 pointings, amounting to 1768 beams. Each pointing was observed for a duration of  $8400$  s, with a sampling time of  $1000 \mu s$ , a centre frequency of 1374 MHz, and a bandwidth of 288 MHz spread across 96 channels. The High Resolution LMC Survey kept the same centre frequency and improved on its predecessor by increasing the length of observation, the bandwidth, and the number of channels to 8600 s, 340 MHz, and 1024 channels respectively. The sampling time was also reduced to 64 μs following the installation of the Berkeley Parkes Swinburne Recorder (BPSR, [Keith et al.](#page-10-25) [2010\)](#page-10-25).

A total of 13 pulsars were discovered in the LMC from the PMPS by [Manchester et al.](#page-10-18) [\(2006\)](#page-10-18), with five found from a reprocessing of the data later on by [Ridley et al.](#page-10-19) [\(2013\)](#page-10-19). With 54 out of 136 pointings completed, the High Resolution LMC survey has yielded four new radio pulsars so far [\(Ridley et al.](#page-10-19) [2013;](#page-10-19) [Hisano et al.](#page-10-20) [2022\)](#page-10-20).

The 'Crab twin' pulsar, PSR J0540–6919 [\(Seward et al.](#page-10-26) [1984\)](#page-10-26), and PSR J0537–6910 [\(Marshall et al.](#page-10-27) [1998\)](#page-10-27) were discovered in Xray observations. PSR J0540–6919 was subsequently observed across various wavelengths, including optical [\(Middleditch & Pennypacker](#page-10-28) [1985\)](#page-10-28), radio [\(Manchester et al.](#page-10-29) [1993a\)](#page-10-29), and in gamma rays [\(Marshall](#page-10-30) [et al.](#page-10-30) [2016\)](#page-10-30), while PSR J0537–6910 remains exclusively detectable at X-rays. Interestingly, [Crawford et al.](#page-10-17) [\(2001\)](#page-10-17) made the serendipitous discovery of PSR J0535–6935 while trying to observe radio signals from PSR J0537–6910. The detection of PSR J0535–6935 was in observation data of lengths 21600 s and 17200 s. The only currently known radio pulsar in the LMC for which radio pulsations have not been discovered by Murriyang is PSR J0523–7125, found in the Australian Square Kilometre Array Pathfinder (ASKAP) Variables and Slow Transients survey [\(Wang et al.](#page-10-31) [2022\)](#page-10-31), with both MeerKAT and Murriyang used afterwards to confirm the discovery. [Table 1](#page-3-0) shows the properties of the known LMC pulsar population.

## <span id="page-1-3"></span>**3 SOURCE SELECTION**

<span id="page-1-1"></span><sup>2</sup> <http://www.trapum.org/>

To optimise our search strategies, we compiled an extensive list of known sources in the LMC that are likely to harbour pulsars. These

<span id="page-1-0"></span><sup>1</sup> <https://www.atnf.csiro.au/research/pulsar/psrcat/> PSRCat v2.3.0

<span id="page-2-1"></span>

Figure 1. Beam maps, made with the Python package APLPY [\(Robitaille & Bressert](#page-10-32) [2012\)](#page-10-32), for Pointing 1 (upper left), Pointing 2 (upper right), Pointing 3 (lower left), and Pointing 4 (lower right), are shown overlaid onto an ASKAP 888 MHz radio continuum survey image from [Pennock et al.](#page-10-33) [\(2021\)](#page-10-33). The outermost black circle is the size of the IB of MeerKAT at the HPBW at 1284 MHz. The central tilings of CBs in black have a 50 per cent overlap, while the remaining tilings, depending on the source of interest, may have either a 50 or 70 per cent overlap (see [subsection 4.1\)](#page-4-1). The red circles are SNRs, the green squares represent known pulsars, the blue circles are GCs, the cyan circles indicate HMXBs, and the orange circles are candidate SNRs (see [Section 3](#page-1-3) and [Table 2\)](#page-4-2). The dashed orange circles in Pointings 1 and 2 show candidate SNRs J0504–6901, J0510–6853, and J0521–6936 from [Bozzetto et al.](#page-9-9) [\(2023\)](#page-9-9) and [Zangrandi et al.](#page-11-0) [\(2024\)](#page-11-0), which had not yet been discovered at the time of observation. In Pointing 1, the SNR N 132D, found at its bottom left, was not tiled due to its proximity to the HPBW of the IB. The pink circle in Pointing 3 represents the error on the position of the known pulsar PSR J0535–6935 [\(Crawford et al.](#page-10-17) [2001\)](#page-10-17). We did not detect this pulsar, possibly because it could be located outside of the CB tilings. The IB of Pointing 3 was centred on the SN 1987A remnant. The red star markers represent the new pulsar discoveries excluding the incoherent beam pulsar.

included SNRs and candidate SNRs [\(Bozzetto et al.](#page-9-10) [2017;](#page-9-10) [Maitra](#page-10-34) [et al.](#page-10-34) [2019;](#page-10-34) [Yew et al.](#page-11-2) [2021;](#page-11-2) [Maitra et al.](#page-10-35) [2021;](#page-10-35) [Kavanagh et al.](#page-10-36) [2022;](#page-10-36) [Sasaki et al.](#page-10-37) [2022;](#page-10-37) [Bozzetto et al.](#page-9-9) [2023;](#page-9-9) [Zangrandi et al.](#page-11-0) [2024\)](#page-11-0), HMXBs [\(Antoniou & Zezas](#page-9-2) [2016;](#page-9-2) [Maitra et al.](#page-10-34) [2019,](#page-10-34) [2021;](#page-10-35) [Haberl](#page-10-38) [et al.](#page-10-38) [2022\)](#page-10-38), globular clusters (GCs, The SIMBAD astronomical

 $database<sup>3</sup>$  $database<sup>3</sup>$  $database<sup>3</sup>$ , [Wenger et al.](#page-10-39) [2000\)](#page-10-39), and pulsar wind nebulae (PWNe, [Manchester et al.](#page-10-40) [1993b;](#page-10-40) [Gotthelf & Wang](#page-10-41) [2000;](#page-10-41) [Wang et al.](#page-10-42) [2001;](#page-10-42) [Gaensler et al.](#page-10-43) [2003;](#page-10-43) [Williams et al.](#page-11-3) [2005;](#page-11-3) [Bamba et al.](#page-9-11) [2006;](#page-9-11) [Haberl](#page-10-44)

<span id="page-2-0"></span><sup>3</sup> [http://simbad.u-strasbg.fr/simbad/](#page-10-44)

<span id="page-3-1"></span>

**Figure 2.** The minimum flux densities at 1400 MHz of the PMPS, the High Resolution LMC Survey, and this work are plotted against pulse period. The shaded regions around the sensitivity curves indicate the ranges of minimum flux density fluctuations, reflecting the pulsar power-law spectral index un-certainty as per [Jankowski et al.](#page-10-45) [\(2018\)](#page-10-45), which is  $-1.6 \pm 0.54$ . The minimum flux densities using Murriyang are slightly better than the literature, but this is based on our best knowledge of the surveys (see [subsection 4.2\)](#page-5-0). We note that the horizontal section of each of the minimum density curves excludes the red noise contribution, which is known to impact slow pulsars at longer integrations (e.g. [Lazarus et al.](#page-10-46) [2015;](#page-10-46) [van Heerden et al.](#page-11-4) [2017\)](#page-11-4). Each of the markers, denoting the 24 radio pulsars discovered in the LMC, has a colour corresponding to the publication where the discovery was documented. The black diamond markers represent the flux densities for PSRs J0523–7125 [\(Wang et al.](#page-10-31) [2022\)](#page-10-31), J0529–6652 [\(Crawford et al.](#page-10-17) [2001\)](#page-10-17), and J0540–6919 [\(Johnston et al.](#page-10-47) [2004\)](#page-10-47). Notably, these pulsars have not been discovered in the main LMC pulsar surveys outlined in this paper. There are five orange circle markers with a blue outline representing pulsars which were reported in [Ri](#page-10-19)[dley et al.](#page-10-19) [\(2013\)](#page-10-19) but discovered in the reprocessed archival PMPS data. One of these 5 blue-outlined orange circles, PSR J0535–66, has a 1400 MHz flux density below the minimum flux densities of the Murriyang surveys, which is due to it being discovered using an integration time of 14400 s [\(Ridley](#page-10-19) [et al.](#page-10-19) [2013\)](#page-10-19). The newly discovered pulsars are represented by the red star markers, with the incoherent beam pulsar having the highest flux density (see [Section 6\)](#page-8-0).

[et al.](#page-10-44) [2012\)](#page-10-44). Below we describe the motivation behind each of these types of astrophysical targets.

#### **3.1 Supernova remnants and candidate supernova remnants**

Given that NSs originate from the aftermath of massive stars going supernova [\(Baade & Zwicky](#page-9-12) [1934\)](#page-9-12), it is intuitive to seek out pulsars within SNRs. Pulsars associated with SNRs are typically young, with examples such as the Crab pulsar and PSR J0540–6919 which are known to emit giant pulses [\(Johnston & Romani](#page-10-48) [2003;](#page-10-48) [Geyer](#page-10-49) [et al.](#page-10-49) [2021\)](#page-10-49). There are more than 60 pulsars that are associated with a SNR [\(Manchester et al.](#page-10-11) [2005\)](#page-10-11). These remnants are distinguished by specific characteristics, including a non-thermal power-law radio spectral index steeper than –0.4, diffuse X-ray emissions, and a [Sii]/Hα ratio equal to or greater than 0.4. Often, if a source has just

<span id="page-3-0"></span>Table 1. Table adapted from [Ridley et al.](#page-10-19) [\(2013\)](#page-10-19) showing the list of the 25 known LMC rotation-powered pulsars along with their spin periods, P, their fluxes at 1400 MHz, *S*1400 MHz, their dispersion measures, DM, and their respective discovery papers [\(Manchester et al.](#page-10-11) [2005\)](#page-10-11). The *S*1400 MHz values, which are not necessarily discovery flux densities, were obtained from [Ridley](#page-10-19) [et al.](#page-10-19) [\(2013\)](#page-10-19), [Xie et al.](#page-11-5) [\(2019\)](#page-11-5), [Wang et al.](#page-10-31) [\(2022\)](#page-10-31), [Hisano et al.](#page-10-20) [\(2022\)](#page-10-20), and [Johnston et al.](#page-10-50) [\(2022\)](#page-10-50). The flux densities for eight pulsars are quoted as lower limits as these are not well localised, as reported in [Ridley et al.](#page-10-19) [\(2013\)](#page-10-19). PSR J0537–6910 is known to solely emit X-ray pulsations.

one of these features, it is categorised as a candidate SNR [\(Bozzetto](#page-9-9) [et al.](#page-9-9) [2023\)](#page-9-9). The LMC hosts more than 80 SNRs and 40 candidate SNRs [\(Zangrandi et al.](#page-11-0) [2024\)](#page-11-0) and to improve our chances of discovering pulsars, we chose to target some of these.

One of these LMC SNRs is arguably the most famous recent supernova that we know of, SN 1987A, a type II supernova located on the fringe of the most energetic star-forming region in the Local Group, 30 Doradus [\(De Marchi et al.](#page-10-51) [2011;](#page-10-51) [Fahrion & De Marchi](#page-10-52) [2024\)](#page-10-52). Since the first detection of neutrinos emanating from SN 1987A [\(Bionta et al.](#page-9-13) [1987;](#page-9-13) [Burrows & Lattimer](#page-9-14) [1987;](#page-9-14) [Hirata et al.](#page-10-53) [1987\)](#page-10-53), and despite decades of multi-wavelength searches (e.g. [Manchester & Pe](#page-10-54)[terson](#page-10-54) [1996;](#page-10-54) [Marshall et al.](#page-10-27) [1998;](#page-10-27) [Zhang et al.](#page-11-6) [2018;](#page-11-6) [Alp et al.](#page-9-15) [2018\)](#page-9-15), the existence of a pulsar in the SNR remains to be proven. [Zanardo](#page-11-7) [et al.](#page-11-7) [\(2018\)](#page-11-7) found some indications for the existence of a compact object when analysing polarisation data, while other studies have detected signs of a PWN in the SN 1987A remnant in both radio [\(Cigan](#page-10-55) [et al.](#page-10-55) [2019\)](#page-10-55), using the Atacama Large Millimeter/submillimeter Array (ALMA), and X-ray frequencies, using the *Chandra*, *NuSTAR*, and *XMM-Newton* telescopes [\(Greco et al.](#page-10-56) [2022\)](#page-10-56). The *James Webb Space Telescope* (*JWST*, [Gardner et al.](#page-10-57) [2006\)](#page-10-57) provided further insight, peeking through the dust and gas clouds of the SNR at infrared wavelengths, with [Fransson et al.](#page-10-58) [\(2024\)](#page-10-58) finding emission lines from highly ionised argon and sulphur which they attributed to being produced by a NS. Regarding pulsed radio emission from the SN 1987A remnant, the current best limit is from [Zhang et al.](#page-11-6) [\(2018\)](#page-11-6), who derived an upper limit of 31 μJy at 1400 MHz by using Murriyang and making use of a signal-to-noise ratio (S/N) threshold of 8. We find

<span id="page-4-2"></span>

that the sky temperature was not taken into account for this upper limit value. If we do include the sky temperature in the direction of the LMC in our calculation, which is 4.0 K at the frequency of 1400 MHz according to the Global Sky Model [\(Zheng et al.](#page-11-8) [2017\)](#page-11-8) as in the Python package  $P_yGDSM^4$  $P_yGDSM^4$  [\(Price](#page-10-59) [2016\)](#page-10-59), we expect an upper limit of 37.2 μJy. Motivated by both this upper limit and our survey sensitivity (see [subsection 4.2\)](#page-5-0), we chose to conduct a fresh search for a radio pulsar in the SN 1987A remnant using MeerKAT.

#### **3.2 High-mass X-ray binaries**

A NS can be recycled through the accretion of matter via Roche-lobe overflow in the case of a low-mass X-ray binary (LMXB), or through stellar winds from a companion star in the case of a HMXB, resulting in X-ray emission during what is known as the X-ray binary phase. In a LMXB comprised of a NS and a low-mass companion, material is drawn from the companion star and the NS can be spun up into the millisecond spin period regime [\(Alpar et al.](#page-9-4) [1982;](#page-9-4) [Radhakrishnan &](#page-10-9) [Srinivasan](#page-10-9) [1982;](#page-10-9) [Tauris & van den Heuvel](#page-10-60) [2006;](#page-10-60) [Papitto et al.](#page-10-10) [2013\)](#page-10-10). Accretion processes are expected to alter magnetic field structures, or suppress the emission mechanism responsible for generating radio emission in NSs. Consequently, radio pulsations are generally not expected at this evolutionary stage [\(Fornasini et al.](#page-10-61) [2023;](#page-10-61) [van](#page-11-9) [den Eijnden & Rajwade](#page-11-9) [2024\)](#page-11-9). Most pulsars found in HMXBs are exclusively X-ray pulsars, and over 80 of them have been discovered in the Milky Way [\(Kim et al.](#page-10-62) [2023\)](#page-10-62). A few radio pulsars have been discovered in systems believed to have evolved from HMXBs (e.g. [Johnston et al.](#page-10-63) [1992;](#page-10-63) [Kaspi et al.](#page-10-13) [1994\)](#page-10-13). With around 50 HMXBs discovered in the LMC, we chose to target some of these sources in view of finding unexpected pulsed radio emission [\(Antoniou &](#page-9-2) [Zezas](#page-9-2) [2016;](#page-9-2) [Maitra et al.](#page-10-34) [2019;](#page-10-34) [Haberl et al.](#page-10-38) [2022\)](#page-10-38).

## **3.3 Globular clusters**

GCs exhibit a significantly larger pulsar population per unit of stellar mass than the Milky Way disc, estimated to be approximately one hundred times greater and predominantly comprised of MSPs [\(Clark](#page-10-64) [1975;](#page-10-64) [Katz](#page-10-65) [1975;](#page-10-65) [Abbate](#page-9-16) [2021\)](#page-9-16). This arises due to the conducive conditions of high stellar densities in GCs, where there is a higher probability for isolated NSs forming binaries and being recycled to MSPs than elsewhere in the Milky Way. With over 150 identified Milky Way GCs, over 300 pulsars have been discovered within 44 of these clusters through various surveys<sup>[5](#page-4-4)</sup> (e.g., [Ransom et al.](#page-10-66) [2005;](#page-10-66) [Pan](#page-10-67) [et al.](#page-10-67) [2021\)](#page-10-67), with a significant proportion discovered by MeerKAT (e.g., [Ridolfi et al.](#page-10-68) [2021;](#page-10-68) [Abbate et al.](#page-9-17) [2022;](#page-9-17) [Ridolfi et al.](#page-10-69) [2022;](#page-10-69) [Chen et al.](#page-10-70) [2023\)](#page-10-70). Notably, the LMC is home to more than a dozen GCs having ages surpassing 11 Gyr [\(Piatti et al.](#page-10-71) [2019\)](#page-10-71), increasing the likelihood of hosting recycled pulsars. Therefore, we targeted some LMC GCs to enhance our chances of discovering binary systems, including MSP binaries.

## **3.4 Pulsar wind nebulae**

PWNe are created through the interaction between outflowing winds emitted by a pulsar and the surrounding interstellar material and they can reside within SNRs. The presence of a pulsar within a SNR can be inferred by observing the interactions of its pulsar wind with the surrounding environment (e.g. [Scargle](#page-10-72) [1969;](#page-10-72) [Bietenholz](#page-9-18) [et al.](#page-9-18) [2004;](#page-9-18) [Gaensler et al.](#page-10-73) [2002\)](#page-10-73). Two LMC pulsars are located within PWNe, namely PSRs J0540–6919 [\(Manchester et al.](#page-10-40) [1993b;](#page-10-40) [Gotthelf & Wang](#page-10-41) [2000\)](#page-10-41), and J0537–6910 [\(Wang et al.](#page-10-42) [2001\)](#page-10-42). Additionally, there are three PWNe in the LMC without associated pulsars. These are situated in SNRs LHG 1 [\(Gaensler et al.](#page-10-43) [2003\)](#page-10-43), DEM N206 [\(Williams et al.](#page-11-3) [2005\)](#page-11-3), and L241 [\(Bamba et al.](#page-9-11) [2006\)](#page-9-11). We aim to observe these PWNe to detect potential associated pulsars over the course of our survey of the LMC.

## <span id="page-4-0"></span>**4 OBSERVATIONS**

#### <span id="page-4-1"></span>**4.1 Setup**

We used the relative positions and the size of the MeerKAT primary beam, the incoherent beam (hereafter IB) which is about 1.1 degrees in diameter at the half-power beam width (HPBW) at the L-band centre frequency [\(Asad et al.](#page-9-19) [2021\)](#page-9-19), to group the selected sources together. The pointing centres were fine-tuned to encompass the maximum number of candidate sources within the IB (as described in [Section 3\)](#page-1-3). Thereafter, we used the MOSAIC software [\(Chen et al.](#page-10-74) [2021\)](#page-10-74) to simulate coherent beam (hereafter CB) maps, consisting of up to 768 beams (see later in this section), for our planned observations, and tiled the sources depending on their apparent sizes in the sky. The central region of the IB, where the sensitivity is highest, was tiled with the remaining CBs that were not targeting any specific source. Typically, to be more sensitive to pulsars, we used a 70 per cent overlap between neighbouring beams for SNRs and 50 per cent for remaining sources. An overlap value of 50 per cent implies that the neighbouring beams intersect at the point where their sensitivity is reduced to half of their maximum. [Table 2](#page-4-2) shows the LMC sources observed in the first four pointings of the survey. We also targeted known radio pulsars that fall within the four pointings, namely PSRs

<span id="page-4-3"></span><sup>&</sup>lt;sup>4</sup> <https://github.com/telegraphic/pygdsm> accessed on 2023 October 3

<span id="page-4-4"></span><sup>5</sup> <https://www3.mpifr-bonn.mpg.de/staff/pfreire/GCpsr.html> accessed on 2024 July 11

J0519–6932, J0535–6935, J0537–69, and J0540–6919. The detections of these pulsars give us an indication of the performance of the survey pipeline, as well as information about radio frequency interference (RFI) present during the observations. [Figure 1](#page-2-1) shows the beam tilings for the four observed pointings.

The TRAPUM backend was used to record, store, and analyse the data taken for each observation. It comprises two user-supplied equipment (USE) backends provided by the Max-Planck-Institut-für-Radioastronomie (MPIfR) and the Max-Planck-Gesellschaft, namely the Filterbanking Beamformer User Supplied Equipment (FBFUSE, [Barr](#page-9-20) [2018\)](#page-9-20) and the Accelerated Pulsar Search User Supplied Equipment (APSUSE, see [Padmanabh et al.](#page-10-75) [2023,](#page-10-75) and references therein). FBFUSE is an advanced beamformer that can produce digitally steerable CBs in real-time, and it is set up to record data in multiples of 4 antennas at a time to be efficient. The data are captured in a filterbank format by APSUSE, a high-end computing cluster that shares its storage with FBFUSE, where they are stored. Each USE has nodes that are capable of both GPU-based and CPU-based processing. We used the core of MeerKAT, comprising 44 antennas clustered over a 1 km radius, as it provides a favourable trade-off between sensitivity and beam coverage [\(Chen et al.](#page-10-74) [2021\)](#page-10-74). Depending on availability, either 40 or 44 antennas were used for our observations. The observations were carried out using the L-band receiver, with frequencies 856–1712 MHz, a bandwidth of 856 MHz, and a central frequency of 1284 MHz. The four pointings were observed on 2022 September 08 (pointings 1 and 2) and on 2023 January 20 (pointings 3 and 4). The data were recorded with 2048 frequency channels and a sampling time of 153 μs, enabling FBFUSE to form up to 768 'tied-array' CBs. A summary of the observation parameters is given in [Table 3.](#page-6-1)

#### <span id="page-5-0"></span>**4.2 Survey sensitivity**

Compared to Murriyang, MeerKAT has approximately four times the antenna gain at ∼2.8 K Jy–1 [\(Bailes et al.](#page-9-8) [2020\)](#page-9-8) for the full array. To assess the differences in sensitivity among various LMC surveys, we employ the modified radiometer equation [\(Equation 1\)](#page-5-1). This delineates a telescope's sensitivity in detecting radio signals, providing the minimum detectable flux density,  $S_{\text{min}}$ , for a pulsar with a spin period, *P*, and effective pulse width, *W*. It is formulated as [\(Dewey](#page-10-76) [et al.](#page-10-76) [1985;](#page-10-76) [Lorimer & Kramer](#page-10-77) [2004\)](#page-10-77):

<span id="page-5-1"></span>
$$
S_{\min} = \frac{\beta \text{ S/N} \left( T_{\text{sys}} + T_{\text{sky}} \right)}{G \sqrt{n_{\text{pol}} \ t_{\text{obs}} \ \Delta \nu}} \sqrt{\frac{W}{P - W}}. \tag{1}
$$

For our survey, the S/N of the detected pulse is taken to be 9.5, which is our minimum spectral S/N cut (see [subsection 4.3\)](#page-5-2), the system temperature contribution,  $T_{sys}$ , is 18 K [\(Bailes et al.](#page-9-8) [2020\)](#page-9-8), the sky temperature contribution, *T*sky, is 4.6 K [\(Price](#page-10-59) [2016;](#page-10-59) [Zheng et al.](#page-11-8) [2017\)](#page-11-8), the sensitivity degradation factor due to the signal digitisation, β, is 1.0 for 8-bit digitisation [\(Kouwenhoven & Voûte](#page-10-78) [2001\)](#page-10-78), *G* is the antenna gain taken to be  $1.84 \text{ K Jy}^{-1}$  for MeerKAT's core,  $n_{\text{pol}} = 2$ is the number of orthogonal polarisations to be summed,  $t_{\rm obs}$  is the observing time, and  $\Delta v$  is the total bandwidth.

[Figure 2](#page-3-1) shows a comparison between the sensitivity curves of previous LMC pulsar surveys and this survey overlaid with the discovery flux densities of known LMC radio pulsars at 1400 MHz  $(S<sub>1400 MHz</sub>)$ . The S/N thresholds were found from their respective papers, or assumed using our best knowledge of the surveys. We used a folded S/N threshold of 10 for [McConnell et al.](#page-10-12) [\(1991\)](#page-10-12), a spectral S/N threshold of 7 for both [Crawford et al.](#page-10-17) [\(2001\)](#page-10-17) and [Manchester](#page-10-18) [et al.](#page-10-18) [\(2006\)](#page-10-18), and a folded S/N threshold of 8 for [Ridley et al.](#page-10-19) [\(2013\)](#page-10-19) and [Hisano et al.](#page-10-20) [\(2022\)](#page-10-20). Therefore, the sensitivity of each survey

does not scale directly with the telescope parameters. We made use of a Fast Fourier Transform (FFT) efficiency factor of 0.7 to convert between spectral S/N and folded S/N [\(Morello et al.](#page-10-79) [2020\)](#page-10-79). We used a sensitivity degradation factor due to digitisation of 1.06 for the High Resolution LMC Survey [\(Ridley et al.](#page-10-19) [2013](#page-10-19) and [Hisano](#page-10-20) [et al.](#page-10-20) [2022\)](#page-10-20), which makes use of BPSR's 2-bit digitisation, and 1.25 for surveys using 1-bit digitisation [\(McConnell et al.](#page-10-12) [1991,](#page-10-12) [Craw](#page-10-17)[ford et al.](#page-10-17) [2001,](#page-10-17) and [Manchester et al.](#page-10-18) [2006\)](#page-10-18). All of the Murriyang surveys had a gain assumed to be  $0.735 \text{ K Jy}^{-1}$  [\(Manchester et al.](#page-10-24) [2001\)](#page-10-24), and a sky temperature of 4.1 K, except for [McConnell et al.](#page-10-12) [\(1991\)](#page-10-12), which had a sky temperature of 17.8 K due to a different centre frequency of 610 MHz, compared to 1374 MHz for the others [\(Price](#page-10-59) [2016;](#page-10-59) [Zheng et al.](#page-11-8) [2017\)](#page-11-8). We assumed a radio power-law spectral index of  $-1.6 \pm 0.54$  [\(Jankowski et al.](#page-10-45) [2018\)](#page-10-45) for converting the minimum flux densities of the surveys to  $S_{1400 \text{ MHz}}$ . The shaded regions in [Figure 2](#page-3-1) capture the uncertainty range corresponding to the radio power-law spectral index. The system temperature was as-sumed to be 44 K based on [McCulloch et al.](#page-10-16) [\(1983\)](#page-10-16) for [McConnell](#page-10-12) [et al.](#page-10-12) [\(1991\)](#page-10-12), and 21 K according to [Manchester et al.](#page-10-24) [\(2001\)](#page-10-24) for both [Crawford et al.](#page-10-17) [\(2001\)](#page-10-17) and [Manchester et al.](#page-10-18) [\(2006\)](#page-10-18). For the High Resolution LMC Survey, the system temperature was taken to be 23 K [\(Keith et al.](#page-10-25) [2010\)](#page-10-25). Where the effective pulse widths and pulsar flux densities for the different surveys were not available in the literature, we assumed an intrinsic pulse width of 2.5 per cent of the pulsar period and considered additional contributions to the observed pulse width to obtain the flux densities. These included the DM smearing,  $t_{DM}$ , the survey sampling time,  $t_{\text{samp}}$ , and the scattering time-scale,  $t_{\text{scatt}}$ . The latter was based on the model by [Bhat](#page-9-21) [et al.](#page-9-21) [\(2004\)](#page-9-21). We used the median DM of the known LMC pulsars of 98.7 pc  $cm^{-3}$  for these calculations and a radio power-law spectral index of –1.6 to convert the flux densities of the known pulsars to *S*1400 MHz. A 2-hour observation with the MeerKAT core achieves a deeper flux sensitivity limit than the PMPS and the High Resolution LMC Survey. For periods greater than 50 ms, our survey achieves ∼3 times the sensitivity of the High Resolution LMC Survey, reaching down to a limiting flux density, i.e., the faintest signal that can be detected from a radio pulsar located at the centre of both the IB and a CB, of 6.3 μJy at 1400 MHz.

## <span id="page-5-2"></span>**4.3 Search**

The TRAPUM pulsar search pipeline consisted of three processes: searching, filtering, and folding. The search process involved the removal of RFI using filtool from the Pulsar $X^6$  $X^6$  suite [\(Men et al.](#page-10-80) [2023\)](#page-10-80). A de-dispersion plan was created using DDplan.py from the PRESTO package [\(Ransom](#page-10-81) [2011\)](#page-10-81). We chose a DM range of  $35-500$  pc cm<sup>-3</sup>, given that for the known pulsars in the LMC, the lowest DM is  $45 \,\mathrm{pc \, cm^{-3}}$  and the highest is  $273 \,\mathrm{pc \, cm^{-3}}$  (see [Ta](#page-3-0)[ble 1\)](#page-3-0). This de-dispersion plan, with step sizes of 0.1 up to a DM of  $334 \,\text{pc cm}^{-3}$ , and 0.2 at higher DM values, was fed into the search pipeline where  $PEASOUP^7$  $PEASOUP^7$  [\(Barr](#page-9-22) [2020\)](#page-9-22), a GPU-based acceleration search software suite, performed the de-dispersion and the periodicity search [\(Morello et al.](#page-10-82) [2019\)](#page-10-82). We configured PEASOUP to search for candidates with periods up to a maximum of 10 s. To increase our sensitivity to pulsars located in binaries with shorter orbital periods where the latter can induce Doppler shifts on the signals causing pulse smearing, the 2-hour observation for each pointing was divided into six segments of 20-min each and a linear acceleration search was

<span id="page-5-3"></span><sup>6</sup> <https://github.com/ypmen/PulsarX> accessed on 2022 September 12

<span id="page-5-4"></span><sup>&</sup>lt;sup>7</sup> <https://github.com/ewanbarr/peasoup> accessed on 2022 September 12

<span id="page-6-1"></span>

<span id="page-6-5"></span>

**Figure 3.** The localisation of PSR J0534–6905 using SeeKAT, where the pulsar was detected in four beams, shown by the black outlines. The inset plot on the bottom left provides a zoomed-in view of the maximum-likelihood position, which is indicated by a red cross. The  $1-\sigma$  and  $2-\sigma$  errors on the position (see [Table 4\)](#page-7-0) are demarcated by the red continuous line and the red dashed line, respectively.

performed on each segment. For pointings 1 and 2, the acceleration search range was chosen to be  $-50$  to  $50 \text{ ms}^{-2}$ , with an acceleration tolerance of ten per cent for the segment searches, while for pointings 3 and 4, to cut down on processing time, we did not perform any acceleration search. The acceleration tolerance parameters ensure the pulse smearing due to acceleration step size stays within ten per cent of total smearing effects [\(Levin](#page-10-83) [2012\)](#page-10-83). The spectral S/N threshold of the FFT was set to be 8 with a maximum of 8 harmonics summed.

After completing the search, we subjected the candidates to a filtering process using candidate  $\frac{8}{\pi}$  $\frac{8}{\pi}$  $\frac{8}{\pi}$ . This filter sifted known RFI signals and then clustered candidates considering spin periods, DMs, beam location, and acceleration values. Through this method, we effectively separated RFI signals, which tend to manifest across the entire field of view, from possible pulsar signals.

Following the filtering, the candidates were folded by making use of psrfold\_fil, a component of the PulsarX package. It used the

DMs, spin periods, and acceleration values of the candidates derived from the search. Candidates with a spectral S/N above 9 were folded for pointings 1 and 2, while for pointings 3 and 4, a higher S/N threshold of 9.5 was used. This modification was made to optimise pipeline processing speed, reducing the number of candidates to fold, while maintaining our pulsar detection capabilities. We plan to keep the spectral S/N threshold as 9.5 for future pointings. Similarly, due to the high number of candidates, we applied a lowest period cut-off of 8 times the sampling time, i.e., 1.216 ms.

The output files containing pulsar candidates generated by the folding process were archive files that are compatible with the PSRCHIVE package [\(Hotan et al.](#page-10-84) [2004;](#page-10-84) [van Straten et al.](#page-11-10) [2012\)](#page-11-10). These files were then classified using the Pulsar Image-based Classification System (PICS, [Zhu et al.](#page-11-11) [2014\)](#page-11-11), which employs deep neural networks for image pattern recognition in pulsar detection. PICS was trained using the Pulsar Arecibo L-band Feed Array (PALFA) survey data [\(Cordes et al.](#page-10-85) [2006\)](#page-10-85), along with data from TRAPUM pulsar surveys [\(Padmanabh et al.](#page-10-75) [2023\)](#page-10-75). PICS assigned a number ranging from 0 to 1 to the candidates, a proxy for probability, with a higher score implying that the candidate showed characteristics more akin to those of a pulsar.

The resulting candidates having altogether a folded S/N above 7, a DM greater than 3, and a PICS score above 0.1 were then viewed using  $\overline{C}$ ANDYJAR<sup>[9](#page-6-3)</sup>, enabling quick sorting and manual classification. Once we identified a candidate as an actual pulsar, we refolded the surrounding beams with the candidate parameters to verify addi-tional detections for confirmation. The SEEKAT Python package<sup>[10](#page-6-4)</sup> (hereafter SeeKAT, [Bezuidenhout et al.](#page-9-23) [2023\)](#page-9-23) improved localisation using these detections (see [Figure 3\)](#page-6-5), requiring a minimum of three detections to do so. It makes use of the S/N, the point spread function (PSF), and the location of the beams with detections to triangulate a position for a pulsar on the sky. We also refolded the detection beam of a pulsar using integer multiples of the pulsar period to potentially improve the discovery S/N ratio and accommodate for harmonics. A full description of the search pipeline can be found in [Padmanabh](#page-10-75) [et al.](#page-10-75) [\(2023\)](#page-10-75) and [Carli et al.](#page-9-5) [\(2024\)](#page-9-5).

## <span id="page-6-0"></span>**5 RESULTS**

The first four pointings of the TRAPUM LMC Survey have yielded seven new pulsars, with four in Pointing 1, two in Pointing 2, and one in Pointing 3. In Pointing 1, one of the pulsars was only detected in the IB and therefore has poor localisation. We call this pulsar the

<span id="page-7-0"></span>Table 4. Properties of the seven new pulsars, including the discovery flux density values (see [subsection 4.2\)](#page-5-0) and the pulse widths at 50 per cent of the peak intensity. The quoted uncertainties in parentheses are on the last digit. The error in each position is the 2-σ output by SEEKAT (see [Figure 3\)](#page-6-5). For the pulsars denoted by a \*, the error in their positions are the sizes of the CBs in which they were found (see [Table 3\)](#page-6-1). The RA and Dec of the incoherent beam pulsar are the same as the centre of Pointing 1.

incoherent beam pulsar, or IB pulsar for short, for the remainder of this work.

The periods of the pulsars range from 278 ms to 1690 ms, categorising them as 'slow' pulsars, or normal pulsars. They have DMs ranging from 79 to  $254.2$  pc cm<sup>-3</sup>, and if we consider the DM contribution from the Milky Way in the direction of the LMC, which is about 53 pc  $\text{cm}^{-3}$  using the NE2001 electron density model [\(Cordes](#page-10-86) [2004\)](#page-10-86), and about 58 pc cm<sup>-3</sup> using the YMW16 electron density model [\(Yao et al.](#page-11-12) [2017\)](#page-11-12), we can conclude that these pulsars are extragalactic and belong to the LMC. The DM range of the new pulsars is also consistent with the previously discovered LMC pulsars, which have DMs between 45 pc  $cm^{-3}$ , which notably contradicts the estimations of the electron density models, and  $273$  pc cm<sup>-3</sup> (see [Table 1\)](#page-3-0). We performed follow-up observations of the new pulsars discovered in pointings 1 and 2, and all of the pulsars were detected again except for the incoherent beam pulsar. The IBs of the follow-up observations were unfortunately not analysed to enable the confirmation of the incoherent beam pulsar, due to the requirement to rapidly delete data. It was also not detected in the IB of Pointing 4, despite the latter overlapping with that of Pointing 1 (see [Figure 1\)](#page-2-1) when processed using the search pipeline. All of the already known pulsars that were located within our pointings (see [subsection 4.1\)](#page-4-1) were successfully detected, with the exception of PSR J0535–6935 (see [Figure 1\)](#page-2-1). We did not detect any pulsed radio emission from the observation of the SN 1987A remnant and the X-ray pulsar PSR J0537–6910 in Pointing 3 (see discussion in [Section 6\)](#page-8-0).

The integrated pulse profiles for the seven pulsars are shown in [Figure 4,](#page-8-1) and they all have a single pulse profile. To determine the pulse width of each new discovery, we made a noise-less pulse template for each pulsar using the paas tool from PSRCHIVE, and we simulated 1000 noise profiles using the off-pulse noise statistics derived from their respective average pulse profiles. We fitted von Mises functions to each pulse profile for every simulated noise pro-file using the fit von Mises routine from PSRSALSA<sup>[11](#page-7-1)</sup> [\(Weltevrede](#page-10-87) [2016\)](#page-10-87), which allowed us to measure the pulse widths at 50 per cent of the peak intensity,  $W_{50}$ , without being significantly influenced by noise. The *W*<sup>50</sup> for each pulsar was obtained by taking the average of the 1000 resultant pulse width measurements. [Table 4](#page-7-0) provides a summary of the properties of the new pulsars and their derived parameters.

#### **5.1 Discoveries**

#### *5.1.1 PSR J0509*–*6838*

PSR J0509–6838 was discovered with a folded S/N of 10.3, obtained from PulsarX (see [subsection 4.3\)](#page-5-2), in the complete 2-hour observation data of Pointing 2, making it the weakest detection out of the seven new discoveries. It was found within a beam of the central tiling of Pointing 2 (see [Figure 1\)](#page-2-1), and further detected in the complete 2-hour data of two surrounding beams, enabling its localisation using SeeKAT. With a period of 278.75 ms, it is the fastest rotating pulsar amongst the seven new discoveries. The  $W_{50}$  is (19.4 $\pm$ 2.7) ms, corresponding to a duty cycle of 7 per cent.

## *5.1.2 PSR J0509*–*6845*

PSR J0509–6845 was discovered with a folded S/N of 13.9 in the complete 2-hour observation data of Pointing 2. It was detected within a beam of the central tiling of Pointing 2, with only one additional detection found in the 2-hour data of the surrounding beams. Consequently, we were unable to achieve a localisation more precise than the size of the coherent beam in which it was detected. The *W*<sup>50</sup> is  $(8.4 \pm 0.8)$  ms, resulting in a duty cycle of 2.7 per cent.

## *5.1.3 PSR J0518*–*6939*

PSR J0518–6939 was discovered with a folded S/N of 16.6 in the complete 2-hour observation data of Pointing 1. It was found within a beam of the central tiling of Pointing 1 (see [Figure 1\)](#page-2-1), and further detected in the complete 2-hour data of two surrounding beams, enabling its localisation using SeeKAT. PSR J0518–6939 has a DM of 254.20 pc  $\text{cm}^{-3}$ , which is the second-highest DM in the LMC, after **PSR J0537–69 with a DM of 273 pc cm<sup>-3</sup> (see [Table 1\)](#page-3-0). The**  $W_{50}$  **is**  $(7.3 \pm 0.7)$  ms, corresponding to a duty cycle of 2.2 per cent.

#### *5.1.4 PSR J0518*–*6946*

PSR J0518–6946 was discovered with a folded S/N of 13.9 in the complete 2-hour observation data of Pointing 1. It was located within a beam of the central tiling. The pulsar was further detected in the

<span id="page-7-1"></span><sup>&</sup>lt;sup>11</sup> <https://github.com/weltevrede/psrsalsa> accessed on 2023 October 25

<span id="page-8-1"></span>

**Figure 4.** The integrated pulse profiles, along with the periods and DMs, of the newly discovered pulsars within MeerKAT's L-band, with each plot representing one full rotation of the pulsar with 128 phase bins. The effective time resolution for each pulsar was less than its pulse width.

complete 2-hour data of two surrounding beams, enabling its localisation using SeeKAT. PSR J0518–6946 has a period of 1.69 s, making it the second-longest period radio pulsar in the Magellanic Clouds, following PSR J0534–6845 with a period of 1.82 s (see [Ta](#page-3-0)[ble 1\)](#page-3-0). The  $W_{50}$  is (40  $\pm$  3) ms, resulting in a duty cycle of 2.4 per cent.

#### *5.1.5 PSR J0519*–*6931*

PSR J0519–6931 was discovered with a folded S/N of 23.4 in the complete 2-hour observation data of Pointing 1, making it the strongest detection amongst the seven new discoveries. It was found within a beam of the central tiling, with only one additional detection found in the 2-hour data of the surrounding beams. With a total of two detections, we were unable to obtain a better localisation than the size of the coherent beam in which it was detected. The  $W_{50}$  is  $(7.5 \pm 0.4)$  ms, corresponding to a duty cycle of 2 per cent.

#### *5.1.6 Incoherent beam pulsar*

The incoherent beam pulsar was discovered with a folded S/N of 11.0 in the complete 2-hour observation data of Pointing 1. It was located outside of the beam tilings of Pointing 1, with a period of 533.97 ms and a DM of 79 pc cm<sup>-3</sup>. The  $W_{50}$  is (24  $\pm$  3) ms, resulting in a duty cycle of 4.5 per cent.

#### *5.1.7 PSR J0534*–*6905*

PSR J0534–6905 was discovered with a folded S/N of 17.4 in the complete 2-hour observation data of Pointing 3. It was found within a beam of the central tiling (see [Figure 1\)](#page-2-1), and further detected in the complete 2-hour data of three surrounding beams, enabling its localisation using SEEKAT (see [Figure 3\)](#page-6-5). The  $W_{50}$  is (25  $\pm$  2) ms, corresponding to a duty cycle of 3 per cent.

## <span id="page-8-0"></span>**6 DISCUSSION AND CONCLUSIONS**

The seven radio pulsars discovered increase the known LMC pulsar population to 32, an increase of ∼30 per cent. They do not seem to be associated with any of the sources listed in [Table 2.](#page-4-2) We crosschecked the positions with the ASKAP 888 MHz radio continuum survey image of the LMC [\(Pennock et al.](#page-10-33) [2021\)](#page-10-33), and we found that PSR J0518–6946 seems to be located within a faint shell of radio emission, possibly linked to the nearby SNR N 120A, although this is not conclusive, with an on-sky angular separation of ∼432 arcsec from the centre of the latter. Similarly, PSR J0518–6939 is also located in a region of radio emission, closer to SNR N 120A. The onsky angular separation in this case is ∼150 arcsec. If PSR J0518–6939 is associated with SNR N 120A, which has an estimated age of 7300– 8000 years [\(Rosado et al.](#page-10-88) [1993;](#page-10-88) [Reyes-Iturbide et al.](#page-10-89) [2008\)](#page-10-89), it would have a maximum average transverse velocity of over  $4000 \text{ km s}^{-1}$ , one order of magnitude higher than the mean velocity of young pulsars, which we take to be ~400 km s<sup>-1</sup> [\(Lyne & Lorimer](#page-10-90) [1994;](#page-10-90) [Hobbs et al.](#page-10-91) [2005;](#page-10-91) [Verbunt et al.](#page-10-92) [2017\)](#page-10-92), and several times higher than the fastest moving pulsars, around 1000 km s<sup>-1</sup> [\(Chatterjee et al.](#page-10-93) [2005;](#page-10-93) [Deller](#page-10-94)

[et al.](#page-10-94) [2019\)](#page-10-94), making the association unlikely. PSR J0534–6905 has a high DM of  $244 \,\mathrm{pc \, cm}^{-3}$ , which can be explained by its location on the outskirts of the star-forming region, 30 Doradus, where there is abundant gas and dust. Future LMC imaging surveys may reveal more about these pulsars and their associations.

The incoherent beam pulsar was detected with a *S*1400 MHz of  $42.3 \mu Jy$  (see [Table 4\)](#page-7-0), which implies it is bright enough to have been detectable in the High Resolution LMC Survey and the PMPS, as seen in [Figure 2.](#page-3-1) A detection within the previous surveys' data would help in framing the localisation and for this reason, we downloaded the Murriyang archival data available from the CSIRO Data Access Portal<sup>[12](#page-9-24)</sup> centred on the coordinates of the IB of Pointing 1, and within a radius of 30 arcmin. We undertook a search using pdmp from PSRCHIVE around the discovery DM, with a range of  $\pm 10$  pc cm<sup>-3</sup>, and discovery period, with a range of  $\pm 10$  per cent. Unfortunately, the searches did not yield any detection of the incoherent beam pulsar within the Murriyang archival data. This could be due to many factors, such as the distribution of the beams of the Murriyang surveys, and variations in the pulsar flux density.

The observation of the SN 1987A remnant with MeerKAT was on day 13,115 after the explosion. The non-detection of radio pulsations from the SN 1987A remnant could mean that the putative NS is still shrouded in substantial clouds of matter. The impact of the surrounding nebula varies significantly with observing frequency, the structure of surrounding dust and gas, and the viewing angle. With time, the ejected material is expected to clear out and could possibly give a better line of sight view of the suspected NS. The ejecta dust from the supernova has not gone through any reverse shock-related changes and it is expected that this could cause some dissipation when it does happen [\(Jones et al.](#page-10-95) [2023\)](#page-10-95). We determine the upper limit for the detection of pulsed radio emission in the SN 1987A remnant as 6.3 μJy at 1400 MHz, since Pointing 3 was centred on the SN 1987A remnant (see [Figure 1\)](#page-2-1). We plan to re-observe the SN 1987A remnant using the S-band receivers of MeerKAT, with frequencies 1.7–3.5 GHz [\(Barr](#page-9-20) [2018\)](#page-9-20), to attempt to mitigate dispersion and scattering effects owing to the dust and gas clouds.

[Crawford](#page-10-96) [\(2024\)](#page-10-96) detected three repeated signals from PSR J0537-6910 at a DM of 103.4 pc cm<sup>-3</sup>. We used pdmp to search the CB data from Pointing 3 corresponding to the location of the Xray pulsar around this DM value, with a range of  $\pm 10$  pc cm<sup>-3</sup>, and the pulsar period with a range of  $\pm 10$  per cent. We unfortunately did not detect any pulsed radio emission from PSR J0537–6910, allowing us to derive the upper limit as 7.7 μJy at 1400 MHz, after correcting for the sensitivity loss due to the offset between the location of the pulsar and the centre of Pointing 3.

The seven new pulsars represent discoveries from the initial four pointings of the 28 currently planned for the TRAPUM LMC Survey conducted using MeerKAT. We save the low-resolution version of the data from all observed pointings for future Fast-Folding Algorithm searches. Follow-up timing observations are underway, and a detailed analysis will be presented in a future paper.

## **7 ACKNOWLEDGEMENTS**

The MeerKAT telescope is operated by the South African Radio Astronomy Observatory, which is a facility of the National Research Foundation, an agency of the Department of Science and Innovation. SARAO acknowledges the ongoing advice and calibration of GPS systems by the National Metrology Institute of South Africa (NMISA) and the time space reference systems department of the Paris Observatory.

TRAPUM observations used the FBFUSE and APSUSE computing clusters for beamforming, data acquisition, storage, and analysis. These clusters were designed, funded, and installed by the Max-Planck-Institut für Radioastronomie and the Max-Planck-Gesellschaft.

This research would not have been possible without the financial support for VP, which came from the National Organising Committee for the International Astronomical Union General Assembly 2024, through the Africa 2024 Scholarship, and the UCT-SKA Doctoral Scholarship.

AP and MB are supported in part by the 'Italian Ministry of Foreign Affairs and International Cooperation', grant number ZA23GR03, under the project 'RADIOMAP - Science and technology pathways to MeerKAT+: the Italian and South African synergy'.

AR is supported by the Italian National Institute for Astrophysics (INAF) through an 'IAF - Astrophysics Fellowship in Italy' fellowship (Codice Unico di Progetto: C59J21034720001; Project 'MIN-ERS'). AR also acknowledges continuing valuable support from the Max-Planck Society.

## <span id="page-9-0"></span>**8 DATA AVAILABILITY**

The discovery PSRCHIVE archive files of the new pulsars can be found on ZENODO at [DOI 10.5281/zenodo.12723576.](https://zenodo.org/doi/10.5281/zenodo.12723576) The TRA-PUM collaboration will share the candidates list upon appropriate request.
