Oligodendroglial NMDA Receptors Regulate Glucose Import and Axonal Energy Metabolism

Highlights
- Oligodendroglial NMDA receptors regulate GLUT1 trafficking and glucose import
- Mouse mutants lacking NMDA receptors from oligodendrocytes are delayed in myelination
- Activation of oligodendroglial NMDA receptor supports the axonal energy metabolism
- Mice lacking oligodendroglial NMDA receptors develop late-onset axonopathy and neuroinflammation

SUMMARY

Oligodendrocytes make myelin and support axons metabolically with lactate. However, it is unknown how glucose utilization and glycolysis are adapted to the different axonal energy demands. Spiking axons release glutamate and oligodendrocytes express NMDA receptors of unknown function. Here we show that the stimulation of oligodendroglial NMDA receptors mobilizes glucose transporter GLUT1, leading to its incorporation into the myelin compartment in vivo. When myelinated optic nerves from conditional NMDA receptor mutants are challenged with transient oxygen-glucose deprivation, they show a reduced functional recovery when returned to oxygen-glucose but are indistinguishable from wild-type when provided with oxygen-lactate. Moreover, the functional integrity of isolated optic nerves, which are electrically silent, is extended by preincubation with NMDA, mimicking axonal activity, and shortened by NMDA receptor blockers. This reveals a novel aspect of neuronal energy metabolism in which activity-dependent glutamate release enhances oligodendroglial glucose uptake and glycolytic support of fast spiking axons.

INTRODUCTION

Oligodendrocytes, best known for making myelin (Emery, 2010; Nave and Werner, 2014), also support the survival of myelinated axons (Griffiths et al., 1998; Kassmann et al., 2007; Lappe-Siefke et al., 2003). Myelin is assembled as a spiral extension of oligodendroglial cell membrane, which requires vesicular transport of membrane material through non-compacted cytosolic channels to the growing tip (Snaidero et al., 2014). In mature myelin, a system of nanometer-wide “myelinic channels” is left behind, the dynamics and dimensions of which were only appreciated with the application of high-pressure freezing (HPF) electron microscopy (Snaidero et al., 2014).

Recently, the identification of metabolic coupling between oligodendrocytes and the axonal compartment, with glycolytic oligodendrocytes providing lactate to axons for aerobic ATP production (Fünfschilling et al., 2012; Lee et al., 2012), has introduced a new paradigm for the interaction of axons and their associated glial cells. However, the concept of glycolytic support by oligodendrocytes (Morrison et al., 2013; Saab et al., 2013) raises the question of how glucose utilization is quantitatively regulated. Since the average spike count rate is the key determinant of axonal ATP consumption, oligodendrocytes need to “know” the spiking activity of myelinated axons, which can differ greatly in vivo (Barry, 2015; Perge et al., 2012). The constitutive overproduction of lactate would result in lactic acidosis, detrimental for white matter function. A plausible preventive mechanism would be that oligodendrocytes “learn” their association with fast spiking axons to adapt their own energy metabolism.

Like unmeyelinated axons (Kukley et al., 2007; Wake et al., 2011; Ziskin et al., 2007) also myelinated axons release glutamate upon spiking, which induces calcium elevations in myelin (Micu et al., 2016). Oligodendrocytes could take trace amounts of glutamate as a proxy for axonal spiking activity and energy needs. Indeed, periaxonal spaces underneath myelin are narrow (<50 nm), and glutamate could reach high local concentrations (Stys, 2011).

Oligodendrocytes express different glutamate receptors, including NMDA receptors of unknown function (Karadottir et al., 2016).
A role for NMDA receptor signaling in oligodendrocyte differentiation and promoting myelination has been suggested, based on in vitro observations (Ji et al., 2013; Lundgaard et al., 2013), which is compatible with neuronal activity stimulating OPC proliferation and myelination in vivo (Gibson et al., 2014; Liu et al., 2012). Recently, axonal activity was shown to induce NMDA receptor-mediated calcium increases in myelin, indicating that adult oligodendrocytes have functional NMDA receptors (Mici et al., 2016). However, conditional mouse mutants lacking this receptor from OPC reveal no major abnormality (De Blasie et al., 2011; Guo et al., 2012).

NR1 is the obligate subunit of tetrameric NMDA receptors, and expression of its gene (Grin1) is higher in OPC than in mature oligodendrocytes (Zhang et al., 2014) but remains detectable throughout adult life (this study). Here, we tested the hypothesis that NMDA receptor signaling to oligodendrocytes is the missing link in coupling axonal activity and ATP consumption to oligodendroglial glucose utilization and lactate supply.

RESULTS

NMDA Receptor Activation Triggers GLUT1 Surface Expression and Enhances Glucose Import in Cultured Oligodendrocytes

Oligodendroglial GLUT1 was localized to intracellular compartments and primary processes (but only weakly to secondary and tertiary processes) and immature myelin membranes (Figure 1A, top). Cultured neurons mobilize glucose transporter GLUT3 in response to glutamate (Ferreira et al., 2011). We therefore asked whether GLUT1, the predominant transporter of oligodendrocytes and astrocytes (Zhang et al., 2014), behaves similarly.

Remarkably, treatment with NMDA triggered GLUT1 redistribution in oligodendrocytes within 30 min, leading to apparent surface expression (Figure 1A, middle) that was efficiently blocked by D-(-)-2-amino-5-phosphonopentanoic acid (D-AP5) (Figures 1A, bottom, and 1C). In contrast, monocarboxylate transporter MCT1 distribution in GLUT1 and GalC. NMDA receptor stimulation mobilizes GLUT1 and increases its cell surface expression, which is blocked by D-AP5. Scale bar, 20 μm.

(Figure 1B) GLUT1 and MCT1 immunoblots following cell surface biotinylation of immunopanned NMDA-treated oligodendrocytes and controls. (C) Quantification of the experiments giving the ratio of GLUT1:GalC in a stained area of n = 3 experiments and 20–24 cells per condition (*p < 0.05, **p < 0.01 one-way ANOVA with Bonferroni’s multiple comparisons test).

(D) Quantification of the experiments in (B), normalizing biotinylated to total protein (p = 0.03, n = 3; paired t test). MCT1 surface expression is unchanged.

(E) FRET imaging of oligodendrocytes expressing a glucose sensor (Takanaga et al., 2008) (FLIU2Pglu-700μs). Intracellular glucose levels (normalized to baseline FRET signals, n = 4) drop with addition of cytochalasin B (CytB, glucose transporter blocker) or increase with iodoacetate (IA, glycolysis inhibitor). Note that intracellular glucose is rapidly phosphorylated and undetectable.

Inset: oligodendrocyte transfected with the glucose sensor and counterstained for MBP. Note that the sensor is mainly located in the soma and main processes. Scale bar, 20 μm.

(F) NMDA receptor stimulation (by applying 100 μM NMDA and glycine) increases FRET signals that can be blocked by the addition of 7CKA and D-AP5 (FInteraction 251, 7,109) = 1.96, p < 0.0001, two-way ANOVA). (G) Quantification of calibrated FRET signals of NMDA-stimulated oligodendrocytes (26–28 min), compared to baseline and cells also receiving 7CKA and D-AP5 (***p < 0.001, one way ANOVA with Bonferroni’s multiple comparisons test).

(H) Immunopanned oligodendrocytes stimulated with NMDA/Gly (25 min) before switching to 2-deoxyglucose (2DG, 10 mM, 5 min). Increased 2DG uptake was blocked by 7CKA and D-AP5 (n = 5 experiments, *p < 0.05, **p < 0.01; paired t test). (I) 13C, 1H-HSQC spectra at 700 MHz corresponding to proton resonance from the culture medium of immunopanned oligodendrocytes 30 min after exposure to NMDA/Gly (top) and controls (bottom). Boxed: lactate signals. Quantification by comparison of the peak volume of lactate methyl group to the internal standard DSS.

(J) Increased lactate following NMDA/Gly treatment, depicted by overlaying the 1D-1H slices of spectra in the lactate methyl signal range. (K) Lactate release after NMDA receptor stimulation increased to 124% ± 4% (n = 4 paired NMR experiments, p = 0.023 paired t test).

In vivo, reduced glutamate signaling might thus affect myelination during development. To study oligodendroglial NMDA receptor function, we crossed mice with a floxed NR1 allele (Tsien et al., 1996) to Cnp1Cre/+ mice (Lappe-Siefke et al., 2003). NR1 (gene symbol Grin1) encodes the obligatory subunit of functional NMDA receptors (Tsien et al., 1996).

In Grin1floxfloxCnp1Cre/+ mice (hereafter termed NR1 mutant or cKO, with Grin1floxfloxCnp1Cre/+ and Grin1floxFloxCnp1Cre/+ being controls), NR1 was lost by immunostaining, as shown for optic nerve (Figures 2A, 2B, and S2A), by qPCR of genomic DNA and by western blot analysis (Figures 2C and 2D). Recombination analysis revealed that at P5, when the optic nerve is already populated with oligodendroglial precursor cells (OPCs), loss of the floxed allele was not yet significant. However, at P10, when many oligodendrocytes had matured and expressed Cnp1, about one-third of the floxed alleles were excised, and recombination reached 62% ± 8% at P96, when myelination is completed, matching the expected proportion of oligodendrocyte in adult optic nerves (Miller et al., 1985). Cre-mediated reporter expression in optic nerves demonstrated that virtually all recombined cells were of oligodendroglial origin (Figures S2B and S2C). NR1 expression in astrocytes and OPCs could account for the remaining 40% NR1 signal of whole optic nerve immunostainings (Figure 2B) or protein lysates (Figure 2D).

In purified myelin from mutant brains, we found a strong reduction of GLUT1 (but not MCT1) compared to controls (Figures 2E, 2F, S1G, and S1H), whereas total tissue GLUT1 was unchanged in NR1 mutants. By immunogold labeling of mature optic nerves, GLUT1 was localized in the myelin sheath, in the outer tongue, and in the paranodal loops (Figure 2G), well positioned for functional glucose uptake into the system of myelinic channels.

GLUT1 abundance in myelin sheaths of optic nerve axons was reduced by 80% in NR1 mutants compared to littermate controls (Figures 2H), in line with its NR1-dependent mobilization in cultured oligodendrocytes.

GLUT1 mRNA is more abundant in mature oligodendrocytes than in precursor cells (Zhang et al., 2014). From CNS white matter samples, we amplified equal amounts of GLUT1 and MCT1 cDNA when comparing mutants and controls, indicating that NMDA receptor signaling does not regulate GLUT1 at the level of gene expression (Figure S1I). Interestingly, we localized MCT1 by immuno-electron microscopy at both the outer and inner tongue of myelin (Figure 2I). Thus, lactate transporters are strategically positioned for taking up and supplying glycolysis products (Füünschilling et al., 2012; Lee et al., 2012).

Phenotypically, mutant mice were normally developed with functional white matter tracts, as shown for the optic nerve (Figure S3), and are long-lived. This suggests that NMDA receptors are not essential for myelination per se, in agreement with earlier reports (De Biase et al., 2011; Guo et al., 2012). However, the paucity of GLUT1 in myelin (Figures 2E, 2F, and 2H) suggested reduced glucose import, which could affect the rate of myelin growth that is metabolically controlled (Rinholm et al., 2011). In the rodent optic nerve, the highest myelination rate occurs during the third postnatal week (Hildebrand and Waxman, 1984) and predicts the highest demands for glucose as a carbon source for lipid synthesis at this time. Indeed, by EM we noted at ages P18–P20 that myelin was thinner, with fewer myelinated axons in the mutant optic nerves (Figures 3B and 3D–3G). This difference was only transient as adult (P70) NR1 mutant optic nerves “catch up” and exhibit a normal myelin sheath thickness (Figures 3C, 3H, and 3I).

Functional Analysis of Myelinated Axons

To study function, we assessed optic nerve conduction at different stages of development by recording compound action potentials (CAPs) ex vivo, comparing NR1 mutant and controls (Figure S4). CAP profiles revealed a transiently reduced conduction velocity, again only at the peak of myelination (age P19–P21) and mainly affecting small caliber axons (Figures S4D–S4F). These are best explained by the delay of CNS myelination (Figures 3D–3I), as nerve caliber and axon numbers were normal (Figures S4J and S4K). The developmental delay of myelination in NR1 mutant optic nerves fits well the unexplained observation that demyelinating lesions repair less well when NMDA receptors are blocked (Li et al., 2013; Lundgaard et al., 2013).

Next, we examined myelinated optic nerves under metabolic stress for their ability to recover from transient oxygen-glucose deprivation (OGD), a well-established model of acute ischemia (Tekkök et al., 2007). Optic nerves were acutely isolated...
and CAPs were recorded ex vivo (Figure 4A, top). In these experiments, all optic nerves maintained conductivity (defined as “CAP area” of 1.0) and, within minutes after OGD onset, displayed block of nerve conduction, as illustrated by the rapid decline of CAP area (Figures 4A and 4B). When re-perfused 60 min later using oxygenated artificial cerebrospinal fluid (ACSF, 10 mM glucose), we determined some persistent loss of conduction in wild-type nerves, a Ca2+-dependent damage to axons (Tekkök et al., 2007). Surprisingly, in NR1 mutant nerves the recovery of axon function was further reduced by 50% (Figures 4C–4E). This confirms that axons readily use lactate for ATP generation (Fünfschilling et al., 2012; Lee et al., 2012; Tekkök et al., 2007). Indeed, in the absence of free extracellular Ca2+, the axonal recovery was almost 100% in control nerves yet remained significantly impaired in NR1 mutants (Figures S6E and S6F). Thus, glucose

**Figure 3. Myelination in the Absence of Oligodendroglial NMDA Receptors In Vivo**

(A–C) High-pressure freezing (HPF) electron microscopy of the developing optic nerve. Overview of optic nerve cross sections from control and NR1 mutant mice at P10 (A), P20 (B), and P70 (C). At early and late stages, NR1 mutant nerves are indistinguishable from controls. A minor hypomyelination is apparent at P20. Scale bars, 0.5 μm (A and B) and 0.2 μm (C).

(D) Electron microscopy of conventionally fixed optic nerves from mutant and controls, with unmyelinated (U), ensheathed (E), and myelinated (M) axons. Scale bar, 1 μm.

(E–I) Axon size distribution and myelin sheath thickness (g-ratio) at P18 and P70.

(E) Diameter spectrum of myelinated axons with relatively more myelinated small caliber axons in control nerves than in NR1 cKO at P18 (**p < 0.001, two-way ANOVA, Bonferroni’s post-test).

(F) Cumulative frequency of g-ratios (low to high) measured for individual optic nerves of each genotype. Note the significant shift to higher g-ratios in P18 NR1 mutants (inset: means ± SEM of all g-ratios for two axon size groups).

(G) At P18, myelinated (M) axons are transiently reduced in mutant optic nerves, unlike the number of unmyelinated (U) and merely ensheathed (E) axons (400–700 axons counted per nerve; n = 3, p = 0.048).

(H and I) Axon size distribution (H) and optic nerve g-ratios (I) are similar in mutants and controls.

Causality of NMDA Receptor Signaling and Glucose Metabolism in Axonal Support

To demonstrate causality between oligodendroglial glucose metabolism and axonal recovery, we asked whether lactate, permeating through MCT1 (Figures 2I), can replace glucose as an energy source and restore conduction independent of prior NMDA receptor signaling. As predicted, using lactate-containing ACSF for reperfusion, optic nerves from NR1 mutants recovered as well as control nerves and even better than in the presence of glucose (Figures 4D and 4E). This confirms that axons readily use lactate for ATP generation (Fünfschilling et al., 2012; Lee et al., 2012; Tekkök et al., 2005; Wyss et al., 2011). More importantly, it also proves that optic nerves in NR1 mutants are not per se more susceptible to axonal injury. We confirmed this experimentally with MOG-induced experimental allergic encephalomyelitis (EAE), associated with secondary axonal dysfunction. Here, we found no difference in the onset of EAE symptoms or in clinical severity (Figures S5B–S5D), as indicated earlier (Guo et al., 2012; Matute, 2010).

During OGD, abnormal Ca2+ entry into the axonal compartment triggers axon loss probably resulting from excessive glutamate signaling caused by reversal of glutamate transporters (Stirling and Stys, 2010; Tekkök et al., 2007). Indeed, in the absence of free extracellular Ca2+, the axonal recovery was almost 100% in control nerves yet remained significantly impaired in NR1 mutants (Figures S6E and S6F). Thus, glucose...
uptake by oligodendrocytes is critical to reenergize axons independent of Ca\textsuperscript{2+}-mediated damage.

We suggest that NMDA receptor signaling to oligodendrocytes enhances incorporation of GLUT1 into oligodendroglial and myelin membranes (providing “hardware” of glycolytic support), specifically around axons of higher electrical activity. Interestingly, when optic nerves were acutely isolated from wild-type mice and tested an hour later, the prior application of D-AP5, 7CKA, or MK801 (30 min before the onset of OGD) did not visibly reduce axonal recovery from OGD (Figure S6F), in line with older reports (Tekkó et al., 2007). This no contradiction to the mutant phenotype in vivo, however, because development and pharmacology operate at different timescales, and it could take hours or days to lose functionally exposed GLUT1 from the myelin compartment. Indeed, wild-type optic nerves maintained for an extended time ex vivo, and then tested for conductivity, revealed an intriguing effect of both NMDA and NMDA receptor blockers. In the presence of glucose and oxygen, their basic conduction properties appeared unchanged after 16 hr (Figure S6G). We then studied axon function under metabolic challenge but chose a more physiological and graded paradigm than OGD. Optic nerves were stimulated by short bursts with a gradual increase in frequency (between 1 and 100 Hz). As expected, the recorded CAPs declined as a function of increasing frequency (Figures 4F). Interestingly, when nerves were preincubated for 16 hr in the presence of 100 μM NMDA/Gly (mimicking glutamate release from spiking axons), high-frequency conductivity was much better maintained (Figure 4F). For example, NMDA-stimulated nerves appeared well able to maintain axonal conduction at 25 Hz, but without prior NMDA exposure axons stimulated at 25 Hz showed a functional decline of about 10% per min. Consistently, the decline of axonal conduction at increasing frequency of stimulation was even more aggravated when NMDA receptors had been blocked before by D-AP5 and 7CKA (Figure 4F). Taken together, these results strongly suggest that non-spiking axons lose oligodendroglial metabolic support over time.

**In Vivo Relevance of Oligodendroglial NMDA Receptor Function**

To confirm our key finding also in vivo, we focused on the spinal cord. Electrical stimulation of dorsal roots (L4) in anesthetized

---

Please cite this article in press as: Saab et al., Oligodendroglial NMDA Receptors Regulate Glucose Import and Axonal Energy Metabolism, Neuron (2016), http://dx.doi.org/10.1016/j.neuron.2016.05.016
mice evoked stable CAPs that could be recorded from the dorsal columns (L1) (Figure 5A). We detected no overt differences between NR1 mutants and controls in spinal conduction properties or axon excitability (Figures 5B and 5C), confirming the overall integrity of myelinated tracts (Figures 5A, inset). Next, we monitored CAP (peak-to-peak) amplitudes following challenges at low (0.1 Hz), medium (10 Hz) and high frequency (100 Hz). At low or medium frequency (for 10 min), we observed no difference between mutants and controls (Figures 5D). However, upon high-frequency stimulation, CAP amplitudes dropped significantly faster in mutant mice (Figures 5E, inset left). When allowed to recover at low frequency (0.1 Hz), CAPs in mutant spinal cords recovered more slowly than in controls (Figures 5E, inset right).

Myelinated axons vary in length, diameter, and firing frequencies, suggesting that their long-term energy demands differ greatly (Perge et al., 2012). We anticipated that NR1 mutant mice with a developmentally reduced presence of GLUT1 in myelin sheaths develop at least some signs of axonal pathology. We therefore examined white matter integrity in different CNS regions of adult NR1 mutants and controls, kept under normal cage conditions (10–12 months) and without specific challenges. While most white and gray matter regions in mutant mice, including optic nerves, appeared devoid of pathology within the first year (data not shown), such changes became detectable in white matter tracts of the medulla (Figures 6A and S7A). In longitudinal sections, we observed an increased abundance of reactive microglia and astrogliosis (Figures 6A–6D). Also in spinal cord cross sections we occasionally noticed reactive microglia in white matter tracts of the dorsal and lateral columns (Figures S7B and S7C). By electron microscopy, we observed myelin delamination and degenerating axons in cervical spinal cord sections (Figures 6E and 6F) that were not a feature of wild-type mice.

The majority of myelinated axons in cortico-spinal tracts fire at a high frequency and comprise a high energy demanding white matter tract (Perge et al., 2012). We therefore performed a motor-behavioral analysis to assess the function of spinal tracts in adult NR1 mutant mice. Indeed, even on a simple rotarod test, 1 year old NR1 mutants revealed a significant deficit in performance when compared to age-matched controls (Figure 6G).

At the age of 19 months, NR1 mutants exhibited a severe neurological phenotype including hind limb clasping, hunchback, and ataxia (Figure 6H) caused by ongoing neurodegeneration, which became visible at 10 months. Signs of neuroinflammation and axonopathy were seen in all CNS white matter tracts (Figures 6I–6L).

DISCUSSION

Oligodendroglial metabolic support can explain why myelinated axons are vitaly dependent on myelin integrity, independent of the myelin function in saltatory conduction (Griffiths et al., 1998; Kassmann et al., 2007; Lappe-Siefke et al., 2003). However, the question arises as to how glycolysis in oligodendrocytes is matched to different axonal energy needs and how excessive lactate production is avoided. Our study yields a novel working model in which oligodendrocytes regulate glucose utilization by using NMDA receptor signals as a surrogate marker for axonal spiking activity (Figure 7).

While NMDA receptors are widely studied in glutamatergic neurotransmission, the role of NMDA receptors in oligodendrocytes has remained enigmatic (De Biase et al., 2011; Guo et al., 2012; Káradóttir et al., 2005; Li et al., 2013; Lipton, 2006; Lundgaard et al., 2013; Miciu et al., 2006; Piñá-Crespo et al., 2010; Salter and Fern, 2005; Yang et al., 2014). In myelin, NR1
is associated with NR2C and NR3A subunits that provide a weak Mg$^{2+}$ block (Burzomato et al., 2010; Das et al., 1998), suggesting that calcium entry does not require prior membrane depolarization. In development, NMDA receptors are most abundant in oligodendrocyte precursors (De Biase et al., 2010; Zhang et al., 2014). Unfortunately, the early functions of glutamate signaling were not revealed by the deletion of NR1 in OPC (De Biase et al., 2011; Guo et al., 2012). It is possible that calcium permeable AMPA receptors compensate functions other than GLUT1 trafficking, which is specifically regulated by NMDA receptor signaling. This is reminiscent of hippocampal LTP, which also requires NMDA receptors and is not compensated by AMPA receptors alone (Tsien et al., 1996).

Oligodendroglial NMDA receptors are localized in specialized microdomains of myelinating processes (Stirling and Stys, 2010; Stys, 2011) and also face the periaxial space (Miciu et al., 2006). Is NMDA receptor-dependent regulation of GLUT1 in oligodendrocytes and the non-compact myelin compartment the same as GLUT4 regulation in other cell types (Bogan and Kandror, 2010)? In adipocytes, insulin-dependent GLUT4 trafficking requires calcium-dependent myosin motors (Yip et al., 2008). We were unable to mobilize GLUT1 with insulin in oligodendrocytes, but when triggered with NMDA, trafficking was expectedly calcium dependent and required a stable microtubule network (data not shown).

With the completion of developmental myelination, glycolysis products become gradually available to support the axonal energy metabolism, which is presumably more critical for fibers with high spiking activity. The ultrastructure of mature myelin is complex with narrow (non-compacted) cytosolic compartments in which glycolysis can take place. Once incorporated into these myelin membranes, glucose transporters are more likely to serve long-term functions than fast (“insulin-like”) adaptations to changing energy needs. Indeed, our ex vivo experiment showed that it takes many hours for oligodendrocytes to metabolically respond to the loss of glutamate signaling. However, activity-dependent regulation of axonal energy metabolism may be clinically relevant, e.g., in the aging brain or in neurodegenerative diseases (“use it or lose it”).

It is therefore of interest that NR1 mutant mice, when kept in standard housing (i.e., without physical challenges), showed signs of neurodegeneration beginning in the medulla and spinal cord at 10 months of age and progressing later to all CNS white matter tracts. Here, visible axonopathy and inflammation are most likely a “tip of the iceberg,” reflecting reduced energy metabolism in (many more) myelinated axons in vivo.

Finally, we note that astrocytes can also support axon function by releasing lactate in the white matter. They have direct access to the vasculature, store glycogen, and rapidly respond to energy deprivation with glycogen breakdown (Brown and Ransom, 2007). Theoretically, astrocytes may compensate some metabolic functions in oligodendroglial NMDA receptor mutants. The regulated metabolic interactions between axons, oligodendrocytes, and astrocytes are increasingly recognized as key for normal white matter function and likely for axon survival in many neurodegenerative diseases.

### EXPERIMENTAL PROCEDURES

#### Mouse Strains

Female Cnp1-Cre mice (RRID: MGI_3015754) (Lappe-Siefke et al., 2003) were crossed to floxed NR1 (gene symbol Grin1) mice (RRID: MGI_2175051) (Tsien et al., 1996). Conditional knockout animals were Grin1<sup>fl<sup>lox</sup>/fl</sup>Cnp1<sup>Cre+</sup> mice. As controls, we used Grin1<sup>Tm</sup>/<sup>Tm</sup>Cnp1<sup>Cre+</sup>, or Grin1<sup>Tm</sup>/<sup>Tm</sup>Cnp1<sup>Cre+</sup> mice obtained as respective littermates. Some of the mice also carried the R26-stop-EYFP reporter gene for Cre activity (RRID: IMSR_JAX_068148) (Srinivas et al., 2001). Mice were maintained on the C57Bl6 background. Experiments were carried out mainly on male mice. Animal experiments were performed according to German, Spanish, and European guide lines for Animal Experimentation.

#### Cell Culture Preparation

Primary mouse or rat oligodendrocyte progenitor cells (OPCs) were isolated from cerebral cortices at P0–P2 as described previously (Barros et al., 2009; McCarthy and de Vellis, 1980). Cells were grown in DMEM (Lonza) supplemented with 10% fetal calf serum. Glutamax (Invitrogen), Penicillin and Streptomycin (Invitrogen) at 37°C, and 5% CO<sub>2</sub>. Following OPC isolation, cells were differentiated for 5 days in Sato’s medium. For all experiments, Glutamax was withdrawn from the growth medium in the last 12–16 hr of differentiation. OPCs utilized for biotinylation assays, 2-deoxyglucose uptake, or lactate release were further purified to 98.2% ± 0.3% by negative selection immunopanning (Barres et al., 1992).

#### Immunocytochemistry

For GLUT1 and MCT1 immunocytochemistry, differentiated cells were treated for 30 min at 37°C with 100 μM NMDA. Glycine as co-agonist for NMDA receptors was already present in the medium. NMDA receptor blockers D-AP5 and/or 7CKA (100 μM) were applied 30 min prior to NMDA stimulation. Plasma membranes of mature oligodendrocytes were labeled with anti-galactocerebroside (GalC) antibody (Millipore Cat# MAB342 RRID: AB_94857) for 15 min at 37°C prior to fixation with 4% paraformaldehyde for 10 min at RT. Cells were permeabilized with ice-cold methanol for 5 min, washed with PBS, and incubated with anti-GLUT1 antibody (Abcam Cat# ab32551 RRID: AB_90565) overnight at 4°C. After washing, cells were further purified to 98.2% ± 0.3% by negative selection immunopanning and analyzed. Data were grouped per experiment and normalized to control condition.

#### Cell Surface Biotinylation

Immunopanned oligodendrocytes were treated with NMDA receptor agonists or antagonists as described above. Cell surface-associated proteins were labeled by incubation with 0.5 μg/ml membrane-impermeable EZ-link Sulfo-NHS-Biotin (Thermo Scientific) at 4°C for 30 min. Following removal of unbound biotin, cells were lysed for 15 min on ice with 1% Triton X-100. 0.2% SDS in PBS (pH 7.4) containing protease/phosphatase inhibitors. To isolate biotinylated proteins, 350–450 μg of lysate was incubated overnight at 4°C with 150 μl of 50% Pierce Streptavidin Agarose Resin in PBS (pH 7.2). After elution of biotinylated material, proteins were resolved by SDS-PAGE and immunoblotted with anti-GLUT1 or anti-MCT1 antibodies as described below.

#### Glucose Sensor Imaging

Rat mixed glial cells (after 8–12 days in culture) were transfected (using Fugene HD, Roche) with glucose sensor FLII12Pglu-700 mD (Mekala et al., 2015) or adding either iodoacetate (glycolysis inhibitor, 1 mM) or cytochalasin B (cytoskeleton modifier, 40 μM).
Figure 6. Late-Onset Neuroinflammation and Axonopathy in NR1 cKO Mice

(A) Indirect signs of neurodegeneration in white matter tracts at 1 year of age and overview (left) of sagittal cerebellum-spinal cord section from NR1 cKO mice. Signs of local inflammation (Mac3 immunostaining) were more obvious in the ventral white matter (vWM) compared to spinal cord gray matter (GM). Higher magnification (region marked by a red rectangle) reveals activated microglia (Mac3). Scale bar, 20 μm. See also Figure S7.

(B) Neuroinflammation in the ventral white matter of NR1 cKO mice confirmed by increased density of cell nuclei (p = 0.029, n = 4, Student’s t test). In adjacent GM, nuclear densities are unaltered.

(C) Quantification of the Mac3+ immunostained area (microgliosis) in vWM of NR1 mutant mice (p = 0.0004, n = 4, Student’s t test)

(D) Quantification of the GFAP+ area (astrogliosis) in vWM of NR1 mutant mice (p = 0.013, Student’s t test).

(legend continued on next page)
2-Deoxyglucose Uptake Measurements

Immunopanned oligodendrocytes differentiated for 5 days were incubated for 25 min in the presence or absence of NMDA/Gly (100 μM) in a modified medium (in mM: NaCl 91.17; KCl 5.37; NaH2PO4 0.91; NaHPO4 0.23; NaHCO3 17.86; MgSO4 0.81; CaCl2 1.8; NaOH 16.7; HEPES 20; glucose 10; adjusted to pH 7.4 with HCl after equilibration with 5% CO2). Then glucose was replaced by 10 mM 2-deoxyglucose (2DG) for 5 min. 2-deoxyglucose-6-phosphate present within the cell was quantified using a commercial kit according to the instructions of the manufacturer (Cosmobio).

Measurements of Lactate Release by NMR

Immunopanned oligodendrocytes were differentiated for 4 days in Sato’s medium containing 25 mM unlabeled glucose and for an additional day in Sato’s medium containing 25 mM U-13C6-glucose. 100 μM NMDA/Gly was added for 30 min at 37°C in modified medium (as above) containing U-13C6-glucose. Conditioned media was immediately collected and snap frozen until NMR analysis. For details on NMR analysis, see Supplemental Information.

Immunohistochemistry

For NR1 labeling, mice were perfused with ice-cold artificial cerebrospinal fluid (ACSF). Optic nerves were isolated and immersion fixed with 4% PFA for 2 hr. For NR1 labeling, mice were perfused with ice-cold artificial cerebrospinal fluid (ACSF). Optic nerves were isolated and immersion fixed with 4% PFA for 2 hr. NR1 antibodies for NR1 (1:500, Millipore Cat# MAB363, RRID: AB_94946) and GAPDH (1:2000, Enzo Life Sciences Cat# ADI-CSA-335-E, RRID: AB_2039148) were diluted in blocking buffer (5% milk) and incubated overnight at 4°C.之后，对免疫染色的组织进行了洗脱，然后与2%的链霉卵白素标记的第二抗体 incubated overnight at 4°C.之后，对免疫染色的组织进行了洗脱，然后与2%的链霉卵白素标记的第二 antibody incubated overnight at 4°C.之后，对免疫染色的组织进行了洗脱，然后与2%的链霉卵白素标记的第二抗体。Protein lysates of optic nerves from individual mice were prepared using the Precellys Ceramic Kit 1.4 mm and the Precellys 24 homogenizer (Peqlab).

Protein Analysis

Protein lysates of optic nerves from individual mice were prepared using the Precellys Ceramic Kit 1.4 mm and the Precellys 24 homogenizer (Peqlab). For Western blotting, 30 μg protein lysate was size-separated on 12% SDS-polyacrylamide gels and blotted onto nitrocellulose membranes following instructions from BioRad. Primary antibodies to NR1 (1:500, Millipore Cat# MAB363, RRID: AB_94946) and GAPDH (1:2000, Enzo Life Sciences Cat# ADI-CSA-335-E, RRID: AB_2039148) were diluted in blocking buffer (5% milk) and incubated overnight at 4°C. Membranes were washed in 0.05% Tween 20 in phosphate buffer (PBS-T) followed by incubation with a horseradish peroxidase-conjugated secondary antibody. Proteins were detected with an enhanced chemiluminescence kit (Western Lightning, PerkinElmer) according to the manufacturer’s instructions. Exposed ECL films (Amersham Biosciences) were scanned at grayscale (300 dpi resolution) using

Figure 7. Schematic Depiction of Oligodendroglial NMDA Receptor Signaling

Working model in which axonal electrical activity in developing white matter tracts constitutes a glutamatergic signal for the surrounding OPC/oligodendrocytes/myelin compartments (1). After myelination, NMDA receptors associated with the internodal paranodal membrane respond to axonal glutamate release as a surrogate marker for increased axonal electrical activity and energy needs, causing (2) the incorporation of additional glucose transporters into oligodendrocytes and myelin and the adaptation of glucose uptake (feed-forward regulation). Glycolysis products (3) are initially used for ATP and lipid synthesis (4). Later, mature oligodendrocytes release lactate (or pyruvate) to fuel the axonal compartment (5) for mitochondrial ATP production (6). Regulation of oligodendroglial glucose uptake by axonal energy needs could help prevent abnormal accumulation of lactate. The possible effect of glutamate on glucose transporters on astrocytes is not shown.
axons were counted for each nerve. Data were grouped per animal. For g-ratio analysis of unmyelinated, myelinated, and ensheathed axons (defined as 1–3 unmyelinated directly immersion-fixed (4% formaldehyde, 2.5% glutaraldehyde). For analysis of optic nerves that were subjected to OGD, nerves were perfusion-fixed (4% formaldehyde, 2.5% glutaraldehyde). For additional sample preparation or cryofixed by HPF and freeze substituted as described in detail ( Möbius et al., 2010 ). For analysis of axonal pathology, additional qPCR and protein analysis, and immuno-EM analyses; P.D., H.S., and E.D.S. performed in vivo spinal cord recordings; K.K. performed myelin preparations, protein analysis, and immunohistochemistry; W.A. performed EAE analysis; F.K. and K.-A.N. supervised the project; A.S.S. and K.-A.N. wrote the manuscript.

Immunoelectron Microscopy

Freshly dissected optic nerves were immersion fixed with 4% formaldehyde and 0.2% glutaraldehyde in 0.1 M phosphate buffer containing 0.5% NaCl. After embedding in 10% gelatin and subsequent infiltration with 2.3 M sucrose in 0.1 M PB overnight, small blocks of gelatin containing optic nerve pieces were mounted onto aluminum pins for ultramicrotomy and frozen in liquid nitrogen. Ultrathin cryosections were picked up with a 1:1 mixture of 2% methylcellulose and 2.3 M sucrose. Sections were incubated with antibodies against GLUT1 (1:100, Abcam Cat# ab32551 RRID: AB_873660) and MCT1 (1:1,000, Millipore Cat# AB1286 RRID: AB_90565) and detected with protein A-gold (10 nm, obtained from the Cell Microscopy Center, Department of Cell Biology, University Medical Center Utrecht, NL), and by anti-chicken immunogold (10 nm, Aurion), respectively. Sections were analyzed with a LEO EM912AB (Zeiss), and digital micrographs were obtained with an on-axis 2048×2048-CCD camera (TRS, Moorenweis). For quantification, 10–12 randomly taken images from three controls and three NRM mutants were assessed. Per image, all myelinated axons and immunogold particles associated with myelinated axons were counted, and a ratio of immunogold particles to the number of myelinated axons was calculated. The mean ratio per animal was then normalized to controls.

Myelin Preparation and Immunoblotting

Myelin was purified as described before (Norton and Poduslo, 1973) from mouse brain homogenate in 0.32 M sucrose. Immunoblotting was performed as described before (Werner et al., 2007). Briefly, 30 µg of protein were separated on 10% SDS-polyacrylamide gels, blotted onto polyvinylidene difluoride membranes (Roche), and incubated with primary antibodies for GLUT1 (1:50, Abcam Cat# ab32551 RRID: AB_873660), MCT1 (1:1,000, Millipore Cat# AB1286 RRID: AB_90565), and SIRT2 (1:2,000) (Dryden et al., 2003). Blots were incubated with horseradish peroxidase-coupled secondary antibodies (Dianova) and developed by enhanced chemiluminescence (Western Lighting ECL, PerkinElmer) using a luminescence imager (Intas).

Electron Microscopy and Morphometry

Optic nerves were acutely removed and either immersion-fixed for conventional sample preparation or cryofixed by HPF and freeze substituted as described in detail (Möbius et al., 2010). For analysis of axonal pathology, animal nerves were perfusion-fixed (4% formaldehyde, 2.5% glutaraldehyde). For structural analysis of optic nerves that were subjected to OGD, nerves were directly immersion-fixed (4% formaldehyde, 2.5% glutaraldehyde). For analysis of unmyelinated, myelinated, and ensheathed axons (defined as 1–3 unmyelinated layers), 4–6 EM images with 12,000× magnification were analyzed for each nerve. Data were grouped per animal. G-ratio analysis, 4–5 random overview pictures were taken at 8,000× magnification, 200 axons analyzed using ImageJ (images were blinded for experimenter). G-ratios (axonal diameter divided by the fiber diameter including the myelin sheath) were calculated from circular areas equivalent to the measured areas of axons and myelin sheath including the axon.

Optic Nerve Recordings

Following anesthesia and decapitation, nerves were gently removed, placed into an interface perfusion chamber (Haas Top, Harvard Apparatus), and superfused with ACSF containing the following (in mM): 124 NaCl, 3.0 KCl, 2.0 CaCl2, 2.0 MgSO4, 1.25 NaH2PO4, 23 NaHCO3, and 10 glucose. Perfusion chamber was continuously aerated by a humidified gas mixture of 95% O2/5% CO2, and experiments were performed at 37°C. For oxygen-glucose deprivation (OGD), the protocol was performed as described previously (Baltan et al., 2008). Briefly, 1–14, July 6, 2016

**In Vivo Spinal Cord CAP Recordings**

For details, see Supplemental Information. Stimulation and recording from spinal cord axons in vivo were performed with bipolar platinum electrodes. Square-wave constant voltage pulses (100 µs) were used to stimulate the dorsal root L4, and CAPs were recorded from the ipsilateral fasciculus gracilis at spinal cord level L1. Dorsal roots were stimulated at different frequencies (0.1, 10, and 100 Hz), and CAP recordings were sampled at 50 kHz. Distance between the electrodes was measured using a thin cotton thread to evaluate conduction velocities. For analysis of axonal firing strength, the peak-to-peak amplitude (of the first and most robust peak of the CAP recording) was monitored over time and normalized to baseline (0.1 Hz).

**Rotarod and Clinical Score**

Mice (10–12 months) were placed on a horizontal rod at 1 rpm and accelerated with 1 rpm every 10 s (three tests per trial). The clinical scores at the age of 18 months were as follows: 0, asymptomatic; 1, hind limb clasp; 2, additionally, hunchback visible; 3, additionally, slipping during walking on a grid; 3.5, additionally, not able to hold on an inverted grid; 4, additionally, hind limb ataxia, not able to hold on an upright grid and reduced righting reflex; 4.5, spastic hind limbs.

**Statistical Analysis**

Inter-group comparisons were done by Mann Whitney t test or two-tailed Student’s t test. For multiple comparisons, data were analyzed with one-way or two-way ANOVA with Bonferroni’s post-test or using linear mixed effects models (lme4 package v.1.1.9; https://cran.r-project.org/web/packages/lme4/). All analyses were conducted through GraphPad Prism 4 or R (v.3.2.2, R Core Team, 2015). The levels of significance were set as *p < 0.05; **p < 0.01; ***p < 0.001. Data are represented as means ± SEM.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes Supplemental Experimental Procedures and seven figures and can be found with this article online at http://dx.doi.org/10.1016/j.neuron.2016.05.016.

**AUTHOR CONTRIBUTIONS**

All authors analyzed data and contributed ideas to the manuscript. A.S.S. performed mouse breeding experiments, histology, qPCR and protein analysis, microscopy, optic nerve recordings, and EM analysis. S.B., A.S.S., and A.T. performed optic nerve recordings; culture experiments and FRET sensor imaging were performed by J.H., I.D.T., A.T., and A.S.S.; NMR measurements and analysis were performed by D.B. and C.G.; W.M. performed HPF-EM and immuno-EM analyses; P.D., H.S., and E.D.S. performed in vivo spinal cord recordings; K.K. performed myelin preparations, protein analysis, and neurologic scoring of aged mice; B.G. and S.L. performed behavioral assessment of visual performance; H.M.J. helped with EM analysis; W.H. contributed to optic nerve protein analysis; A.P.-S., F.P.-C. and C.M. performed EAE analysis; F.K. and K.-A.N. supervised the project; A.S.S. and K.-A.N. wrote the manuscript.
ACKNOWLEDGMENTS

We thank M.J. Barrett for help in statistical analyses. We thank T. Ruhwedel, A. Fahrenholz, U. Bode, F. Rhode, O. López, and H. Gómez for technical assistance, D. Rhode and C. Casper for animal husbandry, and B. Hamprecht for helpful discussions. This work was supported by the DFG (Research Center Molecular Physiology of the Brain/CNMPB to K.-A.N., F.K., W.M., and C.G.), NIH/NIA Grant AG033720 and the American Heart Association National Scientific Development Grant (S.B.), Ministerio de Ciencia e Innovación (grant no. SAF2013-45684-R) and CIBERNEU (C.M.), DFG SPP-1172 (F.K. and K.-A.N.), DFG SFB 984 (F.K.), DFG SFB/Transregio TRR45 (K.-A.N. and F.K.), and an ERC Advanced Investigators Grant (K.-A.N.). A.S.S. is supported by a long-term EMBO fellowship.
