Published online November 5, 2018.

Is there a universal hierarchy of the senses, such that some senses (e.g., vision) are more accessible to consciousness and linguistic description than others (e.g., smell)? The long-standing presumption in Western thought has been that vision and audition are more objective than the other senses, serving as the basis of knowledge and understanding, whereas touch, taste, and smell are crude and of little value. This predicts that humans ought to be better at communicating about sight and hearing than the other senses, and decades of work based on English and related languages certainly suggests this is true. However, how well does this reflect the diversity of languages and communities worldwide? To test whether there is a universal hierarchy of the senses, stimuli from the five basic senses were used to elicit descriptions in 20 diverse languages, including 3 unrelated sign languages. We found that languages differ fundamentally in which sensory domains they linguistically code systematically, and how they do so. The tendency for better coding in some domains can be explained in part by cultural precocciations. Although languages seem free to elaborate specific sensory domains, some general tendencies emerge: for example, with some exceptions, smell is poorly coded. The surprise is that, despite the gradual phylogenetic accumulation of the senses, and the imbalances in the neural tissue dedicated to them, no single hierarchy of the senses imposes itself upon language.

Since Aristotle, it has been supposed that there is a hierarchy of the senses, with sight as the dominant sense, followed by hearing, smell, touch, and taste (13), opening the possibility that some aspects of perception are intrinsically more accessible to consciousness and thus to language. The position of smell has since been further demoted, based in part on insights regarding the evolutionary development of our senses, in which stereoscopic vision, wider eye orbits, and increasing visual cortex have evolved at the expense of the olfactory bulb and olfactory epithelium (14–19). Modern rewokings of the Aristotelian hierarchy give primacy to sight followed by hearing, touch, and then taste and smell (20, 21). Regardless of the precise characterization, the distal senses of vision and audition are privileged at the expense of the lowly proximal senses of touch, taste, and smell (22).

The idea that differential expressibility (or conversely, ineffability) might tell us something specific about the innate architecture of cognition and how the different faculties can “talk” to language is extremely attractive. However, it rests on the presumption that these patterns are universal, and invariant across languages and cultures. Many scholars, for example, have opined that no language will have...
a developed lexicon for smell (23–28). This presumption has been challenged by cross-cultural investigations showing that while English-speakers may indeed display the oft-touted visual dominance, other cultures show a different picture altogether (29). For example, the Jahai—a hunter-gatherer community residing in the rainforests of the Malay Peninsula—find odors just as easy to express as visual entities (30). This raises the question of whether the hierarchy of the senses is universally expressed across languages.

The sign languages are unrelated to each other; they are not from the same language family.
To test this, we explored the coding of percepts involving different senses (vision, hearing, touch, taste, smell) in 20 largely unrelated languages around the world. The languages were sampled to reflect linguistic diversity from each of the major language families (Fig. 1 and Table 1). Many of these languages are spoken by small ethnic groups with distinctive cultures of their own. We included three unrelated sign languages, allowing us to explore the influence of the modality in which language is expressed (vocal or gestural). Obviously, for the deaf native signers, the coding of auditory stimuli had to be omitted in this comparative study.

We explored the five perceptual domains and investigated both color and shape for vision. Color, of course, has a long history of cross-cultural exploration (1, 31); we added shape in our battery of tests to examine whether the predicted primacy of vision generalized across subdomains. Color stimuli were sampled from Munsell color space; basic geometric figures explored shape distinctions; auditory stimuli varied in pitch, loudness, and tempo; tactile stimuli were focused on tactile texture distinctions (e.g., rough, smooth); the basic taste distinctions of sweet, salty, sour, bitter, and umami were sampled; and smell was tested using a standard olfactory stimulus of microencapsulated odors depicting common scents (e.g., onion, smoke). It should be borne in mind that these domains have some intrinsic differences: for example, the psychophysical space for color is 3D, but odor has an unknown multitude of dimensions. Consequently, any conclusions regarding the absolute codability of domains have to take this fact into consideration. However, our main question concerns whether languages differ in their coding of the senses, specifically in the relative expressivity of perceptual domains. If there is variation across languages in how domains encode the senses, this would not be easily explained by intrinsic domain constraints. We return to this issue in Discussion.

All of the language data were collected by fieldworkers committed to long-term documentation of these languages, or by researchers otherwise experts in the languages (Fig. 1 and Table 1) using a standardized “field manual” (32) (Methods). Collaborative fieldwork meant that skilled researchers were fluent in the local languages, and because of their long-term engagement with communities were able to recruit participants in their local habitat. Testing was conducted in local languages, with fieldworkers asking participants to name stimuli in each of the sensory domains. Researchers then transcribed responses according to a standardized coding scheme and identified the main semantic elements that expressed the perceptual domain at hand. For example, for the full response light moss green given to a color chip, the main contentful response was coded as green. The same procedure was used across modalities. The coding process was iterated across languages until we had standardized the procedure. This was necessary because what is coded as distinct words in English, for example, can be coded in a single word in another language with morphology. Take Tzeltal, rizajtzajik—a single response to a red stimulus—it is actually morphologically complex, being made up of the root morpheme for red rizaj, reduplicated with the suffix tik, a morpheme that maintains the adjectival status of the root morpheme, ‘red-red-AJ’, that is, ‘sort of red’ (33). This is another reason why a collaborative endeavor with expert field linguists is necessary for such a project: it optimizes both standardization for language comparison (i.e., making sure languages are coded in equivalent ways), while doing justice to each language’s particulars without carelessly glossing over critical differences. Once all tricky cases had been identified and appropriately treated, a uniform protocol was applied and checked across all languages (SI Appendix, S1).

Results

Relative Codability of the Senses. We asked whether the senses are equally expressive (or, alternatively, ineffable) in all languages. Earlier work in the color domain has operationalized this notion by referring to “codability”; Brown and Lenneberg (34) showed, for example, that length of response (number of syllables or words), reaction times, and agreement across speakers and within speakers over time, all correlated highly, but that agreement across speakers had by far the highest factor loading. They also showed that codability correlated with correct recognition of colors (see also ref. 35), concluding that “more nameable categories are nearer the top of the cognitive ‘deck’” (34). Codability is thus an important measure, rolling in Zipf’s law (frequency of names correlates with brevity) with perceptual accessibility (36).

Following this tradition, we took as our operational definition of codability the degree to which a stimulus was consistently named within a language community. A measure that reflects this is Simpson’s diversity index $I$ (37), borrowed from ecology (where it is used to measure species diversity, taking into account both the types and abundance of species). This measure has been used previously in language comparison, where naming diversity is calculated, taking into account both the type and frequency of labels per stimulus (30, 38). For a given stimulus within a language, if speakers produce $N$ description tokens, including $R$ unique description types from 1 to $R$, each with frequencies of $n_1$ to $n_R$, then Simpson’s diversity index is as follows:

$$D = \frac{\sum_{i=1}^{R} n_i (n_i - 1)}{N (N - 1)}.$$ 

An index of 1 indicates high codability (and low naming diversity)—all respondents produced the same description—whereas 0 indicates low codability (conversely high naming diversity) since all respondents produced different unique descriptions (note: absence of an overt description was treated as a unique type in the following analyses). For each stimulus in each domain, we calculated codability per stimulus per language community, and then compared these values.

Other measures of agreement are also possible, of course, such as the Shannon information index (39) and the “interpersonal agreement” measure used in the classic work of Brown and Lenneberg (34), but these do not adjust for the number of responses from a particular community. In any case, in our sample, the different measures were highly correlated (Shannon, $r = -0.97$; Brown–Lenneberg interpersonal agreement, $r = 0.95$; SI Appendix, S3).

We used mixed-effects modeling in R (40, 41) to test whether there is a universal hierarchy of the senses or, alternatively, whether languages differed. The full model included random intercepts for stimulus, domain, and language, and the interaction between language and domain. Log-likelihood comparison was used to compare the full model to a model without one of those intercepts (see SI Appendix, S4, for further details). The full dataset contained 44,091 descriptions from 313 respondents in 20 languages. We found languages differed in codability ($\chi^2 = 4.6, P = 0.03$), as did perceptual domains ($\chi^2 = 27.8, P < 0.001$). Crucially, however, codability for domains differed across languages ($\chi^2 = 700.0, P < 0.001$), meaning there is no universal hierarchy of the senses (Fig. 2).

A skeptic might argue that the variation we see across languages is mere noise around a universal pattern. If so, a closer examination of the main effect of domain might reveal the pan-human hierarchy of the senses. If you seek a single hierarchy of the senses that generalizes over the whole language sample using a decision tree (clustering) with random effects for language and stimulus type, the following order emerges (from most to least codable): [color, taste] > [shape, sound, touch] > smell, and a permutation test confirmed the same broad pattern: [color, taste] > shape > [sound, touch] > smell (SI Appendix, S4). This was also supported by a Skillings–Mack test on rankings; SI Appendix, S5). Whatever the precise position of shape in this ordering, it is nevertheless

Majid et al.
clear that this overall cross-linguistic hierarchy is not the widely presumed Aristotelian one.

This generalized ranking of the senses across languages does not do justice to the attested cross-cultural variation in the hierarchy of the senses. In fact, out of 20 languages, there are 13 unique rankings of perceptual domain by mean codability (Fig. 3). In Malay, for example, shape is the most codable of the senses on average and smell is the least codable, but in Umpila the exact opposite pattern holds—smell is the most codable and shape is the least. The attested unique rankings are fewer than would be expected by totally random sampling (permutation $z = -6.5, P < 0.001$), suggesting that the ranking of the senses is not entirely arbitrary, as also suggested by the decision tree analysis above. Across this diverse sample, no language had a domain ranking compatible with the predicted Aristotelian order (sight > sound > touch > taste > smell; Fig. 3). The closest to this hierarchy was English, which application of Spearman’s footrule showed was closer to the predicted order than would be expected by chance ($P = 0.01$; SI Appendix, S5). All other languages showed no greater fit to the Aristotelian order than would be expected by chance (SI Appendix, S5).

As discussed in the Introduction, the senses differ in their inherent psychophysical dimensionality. Color is 3D, taste is arguably 4D (42, 43), and sound (leaving aside timing and timbre for a moment) is 2D (44, 45), whereas shape, touch, and

Fig. 2. Boxplots of codability (measured by Simpson’s diversity index) plotted by domain and language (0 indicates low codability; 1 indicates high codability). English shows the predicted high codability for color, shape, and sound, and low codability for touch, taste, and smell, but other languages exhibit different hierarchies.

Fig. 3. The hierarchy of the senses across languages according to the mean codability of each domain, with the presumed universal Aristotelian hierarchy on Top. There is no universal hierarchy of the senses across diverse languages worldwide.
Factors that explain codability: (A) Codability is higher for a domain if more abstract terms are used to refer to it (regression line from a mixed-effects model). (B and C) Codability is higher for larger populations (raw data with regression line from a mixed-effects model) and communities with formal schooling (C). (D) Codability of sounds is higher for communities with specialist musicians. (E and F) Codability for shape is higher for communities with more access to formal schooling (E) and patterned pottery (F). (G) Codability for angular shapes is higher for communities that live in angular houses. (H) Hunter-gatherers have higher codability for smell than other communities.

To summarize, while vision and sound may be privileged in English, the hierarchy of the senses, as revealed when sampling the diversity of the world’s languages, is clearly not the Aristotelian one.

What Determines the Variation in Codability? If there is not a universal hierarchy of the senses, then what determines the variation found? A list of a priori hypotheses was compiled about external factors, both demographic and cultural, that could influence codability in each domain. If, as Howes (50) eloquently asserts, the sensorium is “the most fundamental domain of cultural expression, the medium through which all values and practices of a society are enacted,” then we ought to see a relationship between specific cultural practices and codability in language (see also ref. 51). To test this, a targeted ethnographic questionnaire was constructed focusing on cultural practices that might predict codability, focusing on each sensory modality separately. Questions included, for example: Does the community use traditional paints or dyes? Is there instruction/training for musical participation (relevant for communicating about sounds)? Do members of the society make pottery, and if so is it patterned? (See SI Appendix, S2, for full set of questions.) In addition, macrofeatures such as population size, environment, etc. were also tested.

To test the effects of these parameters, they were added as fixed effects into the mixed-effects model described above (SI Appendix, S6). We first tested for global effects of macrodemographic features and overall codability across perceptual domains, and found that speakers of languages with a greater number of speakers [estimates from source (53)] had higher agreement across all domains (for a population of 100, estimated mean codability M = 0.14; for a population of 1 million, M = 0.24; P = 0.03), a non–self-evident result. There was a marginal effect of the level of formal education available in the community too: codability was higher with more formal education (high formal schooling availability, M = 0.48, low availability, M = 0.29; P = 0.057). However, there was little evidence of a close tie between overall codability and macrovariables such as mode of subsistence, ecology, or environment.
We next tested for specific associations between cultural and macrofeatures with codability of each perceptual domain. As with the macrofeatures, only a handful of cultural practices showed reliable associations with codability (Fig. 4). In particular, the codability of shape stimuli was higher in communities that make patterned pottery (make patterned pottery, $M = 0.51$; do not make patterned pottery, $M = 0.22$; $\chi^2 = 9.61, P = 0.002$) and have higher levels of formal education (high education, $M = 0.51$; low education, $M = 0.19$; $\chi^2 = 6.78, P = 0.03$). In addition, communities that live in square or rectangular houses have better codability for angular shapes than communities living in round houses (angular houses, $M = 0.35$; round houses, $M = 0.01$; $\chi^2 = 3.93, P = 0.04$).

Sound received higher codability in communities with specialist musicians (specialist musicians, $M = 0.27$; no specialist musicians, $M = 0.11$; $\chi^2 = 4.10, P = 0.04$). One final predictor of linguistic codability from cultural parameters appeared in the domain of smell, where subsistence type was a significant predictor ($\chi^2 = 23.7; P < 0.001$): hunter-gatherers had higher codability ($M = 0.31$) than non-hunter-gatherers ($M = 0.10$), consistent with previous studies investigating smell in hunter-gatherer societies (30, 54).

**Types of Responses.** In addition to examining agreement in naming, we can ask whether certain domains are more likely to have dedicated lexical resources; another measure of ineffability (55). For example, the hunter-gatherer Jahai predominantly name both colors and odors with domain-specific abstract terminology, whereas English speakers in the same paradigm use basic color words, but ad hoc source-based descriptions for smells (30). So we examined the sorts of strategies speakers of each language used across perceptual domains.

Once researchers had established the main contentful response for each stimulus, they coded whether each individual participant’s response was abstract, that is, a descriptive response that captures the domain property (e.g., color, red, green, blue; smell, musty, fragrant; texture, smooth, rough); source-based, that is, referred to a specific object/source (e.g., color, gold, silver, ash; smell, vanilla, banana; texture, fur, silk, beads); or evaluative, that is, gives a subjective response to the stimulus (e.g., nice, horrible, lovely) (SI Appendix, S1). To test differences between response types across domains, a Monte Carlo Markov chain generalized multinomial linear mixed model was used on first responses only (56), predicting type of response by domain with random intercepts for subject and language (as well as stimulus, and respondent (SI Appendix, S7)).

Across the board, abstract descriptions were more likely to be used than source-based descriptions (mean percentage of types within each language: abstract, $M = 71$%; source-based, $M = 27$%; $P < 0.001$) or evaluative descriptions (evaluative, $M = 3$%; $P < 0.001$; Fig. 5). A mixed-effects model testing whether signed languages used a distinct type of response strategy showed no overall effect of the modality of the language; that is, sign languages were not a distinct group (SI Appendix, S7). As expected, if a group of speakers were more likely to use abstract terms to refer to a domain, then the codability of that domain was also higher ($r = 0.34, \chi^2 = 15.0, P < 0.001$; Fig. 4A).

Compared with color, other domains were relatively more likely to elicit evaluative descriptions (all $P < 0.005$), except for shapes, which elicited proportionately more source-based descriptions (all $P < 0.01$). Smell was significantly more likely to elicit evaluative descriptions than other domains ($P < 0.005$), consistent with the idea that odor is predominantly distinguished along hedonic lines (57, 58). Only sound was more likely to elicit abstract descriptions than color ($P < 0.005$), but it notably departed from color and other perceptual domains in predominantly recruiting metaphor for expression.

It is oft-stated that all languages use a high–low metaphor to describe variation in pitch (59–62), and this ubiquity of linguistic encoding reflects the fine-tuning of ear anatomy to the environmental statistics of auditory scenes (62). In our sample of diverse languages, however, the most prevalent way to talk about variation in pitch was through the equivalent of a big–small metaphor instead (seven languages), followed by high/low (four languages) and thin/thick (four languages). Variations in loudness also primarily elicited a big–small metaphor, followed by pairs of nonantonymic contrasts: for example, loud–soft, sharp–soft, strong–soft, strong–small. This suggests that the most “natural” mapping for sound contrasts may, in fact, reside in size rather than spatial location.

**Discussion**

We conclude that the faculty of language does not constrain, due to intrinsic cognitive architecture, the degree to which different sensory domains are richly coded. Instead, the patterns we found suggest that the mapping of language onto senses is culturally relative. For each perceptual modality, there are communities that excel at linguistic expression and those that seem to struggle to put them into words (Fig. 2): American Sign Language and

---

**Fig. 5.** Strategies for describing perceptual stimuli across languages. For each domain and language, the proportion of abstract, source-based, and evaluative responses are plotted.
English speakers showed high codability for colors, but Kata Kolok signers and Yéli Dnye speakers struggled, using varied ad hoc source descriptions; Umpila and British Sign Language participants struggled to name tastes, whereas Farsi and Lao speakers were in total agreement with each other in how to name each tantast. Note also that the modality of language did not predict codability either; while American Sign Language and British Sign Language looked alike in some ways, Kata Kolok—a village sign language—showed distinct linguistic coding of the senses.

A caveat to this rampant variation is the almost uniformly poor coding of smell across communities (Figs. 2 and 3) and its heavy reliance on source-based descriptors (Fig. 5). This could reflect the posited “weak link” between smell and language (27, 28), which has led scholars to call olfaction the “muted sense” (63). Main effects such as these are difficult to interpret, however, since low codability could be put down to poor selection of stimuli; although counter to this possibility, these odor stimuli have been used reliably in cross-cultural studies in the past (64). More generally, other studies have shown that odors can be as codable as colors, in particular for hunter-gatherers (30, 54). In this respect, it is striking to see that the hunter-gatherer Umpila from Australia also demonstrated higher codability for smells than colors, suggesting even within the domain of olfaction, there is significant cultural variation.

Overall, we found codability was higher for larger populations, but this observation is not straightforward to interpret. It is tempting to suggest that larger communities with a higher likelihood for meeting strangers have a greater need for more specific vocabulary, while small communities can rely more on common ground and shared personal history. However, in our study, population size represents the number of speakers a language has globally, not the size of the community that was sampled. While the two measures are the same for small communities like Umpila or Kata Kolok, they are very different for global languages like English. The variable may instead be a proxy for level of industrialization. Indeed, population size increases significantly with complexity of subsistence type in our sample [Kruskal–Wallis χ² (4) = 12.0, P = 0.02]. Population size may also be a proxy for more centralized states: political centralization is more likely with larger populations who have higher rates of literacy, standardized education resources, and wider access to canonical culture. In our study, we found evidence consistent with a link between codability, availability of formal education, and the intrinsic structure of perceptual pathways, their cumulative phylogenetic history, and the sheer amount of neural tissue dedicated to each might have been expected to heavily imprint accessibility to consciousness and thus the nature of the corresponding linguistic coding. Instead, there is neither a fixed hierarchy of the senses, nor a uniform bifurcation between well-codded distal senses (vision, audition) and the more ineffable, more proximal senses (olfaction, and the haptic and gustatory senses). Rather, either by cultural tradition or by ecological adaptation, each language has come to concentrate its efforts on particular sensory domains.

Methods

Sample. We collected data from 20 geographically, typologically, and genetically diverse languages (shown in Fig. 1 and Table 1). The data were collected and treated according to the ethical guidelines of the American Psychological Association, and the protocol was approved by the Ethics Assessment Committee at Radboud University. Informed consent was obtained in writing or orally as appropriate to each community. The data come from both small-scale communities, as well as large urban populations. The communities are diverse in their mode of subsistence, including nomadic hunter-gatherers and pastoralists, as well as industrial and postindustrialist societies.

Materials. To assess codability for each perceptual modality, a standardized set of materials was constructed according to established psychophysical dimensions (32). There were two different tasks for the visual modality. For color, 80 chromatic Munsell color chips were selected; these were 20 equally spaced hues at 4° of brightness at maximum saturation. On a separate occasion, focal colors were also elicited, using a focal color card. This was a single card with small circles of the same 80 chips used in the free naming laid out according to hue and brightness, plus 4 achromatic chips (67). Participants were also screened for color blindness using Ishihara plates. For shape, there were 20 black-and-white stimuli presented in a booklet, which included circles, squares, and triangles—“good” forms according to Gestalt principles—as well as forms that would not constitute good forms, such as a shape that resembled a flower. Shape stimuli were presented in 2D and 3D variants. Some pages included more than one exemplar. The auditory stimuli consisted of 20 audio files that varied in perceived loudness, pitch, and tempo. The stimuli were corrected for perceived loudness—that is, the rising tones had the same sone values, and the loudness scale was corrected to make pitch constant. In the tactile modality, we focused on surface touch, specifying tactile textures were 10 textures, each paired with a tactile card. Finally, for taste, we used the Brief Smell Identification Test, a booklet with scratch-and-sniff common odorants, devised for cross-cultural use (68). The test itself is designed to be administered using a forced-choice format, but we were interested in people’s free responses and so all text was covered using white tape.

Procedure. Researchers were provided with a manual describing the background and providing the instructions for running each task (32). Researchers translated the instructions into the target language so that the experiment was conducted in the speaker’s native language. For each perceptual modality, participants were asked the equivalent of What does this sound/sound like? etc. is this? In languages where there was not a superordinate term available (equivalent to color, for example), other formulations were used, such as How has it been dyed? How does it strike the eye? The final questions were always the default way of eliciting the target domain within the language. Researchers were instructed to audio/video-record sessions for later transcription and coding.

For each domain, the stimulus materials were presented in a single random order across populations, to minimize the effects of order across languages.

PSYCHOLOGICAL AND COGNITIVE SCIENCES

COLLOQUIUM

PAPER
Researchers were instructed to run the tasks in the following order: color, shape, sound, touch, smell, and taste. On occasion, it was not possible to run the experiment in a single sitting and so the experiment was divided into separate sessions. Comparable sound descriptions for auditory stimuli could not be collected for the three sign languages. There are also no data for sound from Yurakaré due to technical problems in the field. It was also not possible to elicit taste descriptions in Mian and Semai as participants did not consent to imbib the taints (primarily due to fear of witchcraft).

Coding. Researchers transcribed the data they had collected into the established orthography of the language. For Farsi and Cantonese, a standardized roman orthography was used for ease of comparison. The three sign languages were glossed into English following the usual conventions. Participants’ full responses were transcribed, and then for each stimulus the main contentful responses were coded, as well as any modifiers or hedges, using a standardized coding protocol (SI Appendix, S1). So, for example, for the full response light moss green, the main contentful response was coded as green, and light and moss were coded as modifiers. The same procedure was used across modalities.

ACKNOWLEDGMENTS. For advice on sound stimuli, we thank Holger Mitteler, and for color, Debi Roberson. Thanks also to Erica Reencken, Nan van de Meerendonk, Nikkie de Jong, and others for assistance with stimulus preparation. This work was funded by the Max-Planck-Gesellschaft. A.M. was supported by a KNAW Ammodo Award. S.G.R. was supported by Leverhulme Early-Career Fellowship ECF-2016-435. American Sign Language data collection was supported by NIH Grant R01 DC010997. British Sign Language data collection was supported by Economic and Social Research Council of Great Britain Grants RES-620-28-6001 and RES-620-28-0002 (Deafness Cognition and Language Research Centre), with the assistance of Adam Schember, Breish Rowe, Neil Fox, and Ye Tian. Additional support was provided by National Science Foundation Grant BCS 1647219 for a workshop leading up to the Sacker Colloquium.
