Vision dominates in perceptual language: English sensory vocabulary is optimized for usage

A B S T R A C T

Researchers have suggested that the vocabularies of languages are oriented towards the communicative needs of language users. Here, we provide evidence demonstrating that the higher frequency of visual words in a large variety of English corpora is reflected in greater lexical differentiation—a greater number of unique words—for the visual domain in the English lexicon. In comparison, sensory modalities that are less frequently talked about, particularly taste and smell, show less lexical differentiation. In addition, we show that even though sensory language can be expected to change across historical time and between contexts of use (e.g., spoken language versus fiction), the pattern of visual dominance is a stable property of the English language. Thus, we show that across the board, precisely those semantic domains that are more frequently talked about are also more lexically differentiated, for perceptual experiences. This correlation between type and token frequencies suggests that the sensory lexicon of English is geared towards communicative efficiency.

1. Introduction

The vocabularies of languages appear to be geared towards the communicative needs of their speakers. In the domain of color, for example, Berlin and Kay (1969) famously suggested that languages only have a small set of color words that tend to cluster around similar perceptual foci across languages (see also Cook, Kay, & Regier, 2005). Indeed, recent evidence indicates that basic color terms are not randomly distributed across the color spectrum, but rather partition it in a way that is most efficient to refer to colors in human environments. Griffin (2006) showed computationally that basic color terms such as red, blue and green produce better color categorization performance of natural images than other color categorization systems, while Yendrikhovskij (2001) found that natural image statistics reveal color clusters closely aligned with the color terms frequently found in the world’s languages. Similarly, Gibson et al. (2017) showed speakers more commonly talk about warm-colored objects in the world, and consequently languages have more dedicated means to talk about ‘warm’ colors.

Similar adaptations to language use have been demonstrated in other conceptual domains. One linguistic “signature” of being geared towards efficiency in usage is when so-called “type” and “token” frequencies are correlated with each other (e.g., Regier, Carstensen, & Kemp, 2016). Type frequencies measure the number of unique word types within a given domain, i.e., how lexically differentiated a domain is. Token frequencies measure how frequently each unique word type is used. A positive correlation between type and token frequencies across conceptual domains indicates that the lexicon of a language has more words precisely for those concepts that speakers also talk about more frequently. Moreover, a correlation between type and token frequency is doubly impressive because if a conceptual domain is broken up into more distinct word types, we may expect each type to be less frequent. If, however, type and token frequencies are positively correlated, then this indicates an even greater need to talk about a given conceptual domain. Regier et al. (2016) showed that languages spoken in relatively colder climates are more likely to distinguish between the concepts ‘ice’ and ‘snow’ (type frequencies), and they also more frequently refer to these concepts (token frequencies of both types). On the other hand, languages spoken in warmer climates are more likely to collapse the ice/snow distinction. Similarly, Warriner and Kuperman (2015) showed that English speakers use positive words such as pleasure more frequently than negative words such as disgust, and they similarly showed that the English language also has more distinct positive word types in the lexicon.
These studies demonstrate how the lexicons of English and other languages are geared towards communicating effectively about various conceptual domains, such as color and ice/snow. Here, we investigate how English is optimized for communicating about our sensory experience more generally. In particular, evidence from different disciplines, including cognitive psychology (reviewed in Stokes & Biggs, 2015), anthropology (e.g., Classen, 1993, 1997), linguistics (e.g., Levinson & Majid, 2014; Viberg, 1983), and philosophy (Keller, 2016; Korsmeyer, 1999), suggests that vision is the most important sensory modality, at least in Western cultures (Majid et al., in press). Our study examines whether the structure of the English lexicon and the way it is used corresponds to this visual dominance in perception. Does English feature more words for visual concepts compared to the other senses? And do speakers use these words more frequently?

1.1. Visual dominance in perception

The hypothesis that English is optimized for the communication of visual concepts is based on multiple strands of evidence which together suggest that vision is the dominant human sense. In particular, demonstrations of “visual dominance” in perception (for review see Stokes & Biggs, 2015) are persuasive. For example, in the so-called “ventriloquist effect”, the location where something is seen overrides the location where something is heard (Alais & Burr, 2004; Pick, Warren, & Hay, 1969; Welch & Warren, 1980). Additionally, the influence of vision extends to the other senses: How something is seen modulates how something is felt more strongly than the other way around (Hay & Pick, 1966; Rock & Victor, 1964), and vision can also influence how something is tasted or smelled (Hidaka & Shimoda, 2014; Morrot, Brochet, & Dubourdieu, 2001; Shermer & Levitan, 2014). These studies demonstrate the capacity of vision to profoundly affect how the other sensory modalities are perceived, more so than the reverse. Moreover, when people integrate information across senses, visual information is often privileged over other sensory modalities (e.g., Spence, Parisé, & Chen, 2012). People also find it easier to perform mental imagery in the visual modality than in other modalities (e.g., Brower, 1947; Kosslyn, Seger, Pani, & Hillger, 1990). Finally, visual dominance is arguably indicated in the anatomy of the human brain, with studies suggesting that vision occupies the largest part of cortex (Drury et al., 1996; Palmer, 1999).

1.2. Visual dominance reflected in language

Given the dominance of vision in perception, the hypothesis that languages adapt to communicative need predicts that languages should be geared towards talking about visual concepts, compared to the other senses. Indeed, in linguistics, the idea that language may exhibit visual dominance is not a new one (see Levinson & Majid, 2014), with Buck (1949: chap. 15) already noting in his Indo-European dictionary that for English verbs, there are more agency distinctions for the visual (to see, to look, to look at) and auditory modality (to hear, to sound, to listen) than for the gustatory and olfactory modalities. For example, an English speaker lexically distinguishes between it looked good and she saw it, but not between it smelled good and she smelled it. This work was extended by Viberg (1983), who demonstrated that across several languages and language families, verbs of visual perception are indeed more lexically differentiated than perceptual verbs for other sensory modalities (see also Evans & Wilkins, 2000). Other researchers have argued that visual verbs are also more likely to be semantically extended compared to verbs for the other sensory modalities, as when speakers say I see you to mean ‘I understand you’ (see Caplan, 1973; Matlock, 1989; Evans & Wilkins, 2000; Sweetser, 1990; Ibarretxe-Antuñano, 2008). In addition, Viberg (1993) showed that visual verbs in English have higher token frequencies in text corpora, a finding that was extended to everyday conversation across 13 different languages by San Roque et al. (2015).

1.3. Current study

These studies are consistent with the hypothesis that visual dominance in perception and human behavior corresponds to visual dominance in the vocabularies of English and other languages, such that there are a greater array of verbs for vision-related concepts. Moreover, speakers use these different verbs more frequently than those of the other, less differentiated senses. But just how deep and pervasive is the perceptual dominance of vision in language?

In the current study, we tested whether visual dominance in English extends across the sensory vocabulary, including adjectives such as blue, soft and fragrant, and nouns such as music and reflection. Our analysis also spans multisensory words such as large and harsh, which clearly describe perceptual content, but not perceptual content exclusive to just one modality (see Lynott & Connell, 2009; Winter, 2016b: chap. 2). We also examined whether visual dominance was robust across registers—such as fiction or academic writing—and whether the pattern is stable across time. Across our analyses, we investigated both unique types of words, as well as their token frequencies. Our results show—across lexical class, register, and historical time—that the English language contains more visual words, and that speakers use these words more frequently. In comparison, English features fewer distinct taste and smell words, and speakers tend to verbalize taste, and particularly smell, concepts less frequently. The fact that precisely those sensory modalities that are more frequently talked about also have more semantic distinctions supports the view that English perceptual vocabulary is adapted towards the communicative needs of its speakers.

2. Methods

2.1. Using modality norms to characterize sensory modalities

We utilized native speaker ratings to quantify the degree to which a word was visual, auditory, tactile, gustatory or olfactory. Such “modality norms” have been collected by many researchers (including Lynott & Connell, 2009, 2013; Speed & Majid, 2017; van Dantzig, Cowell, Zeelenberg, & Pecher, 2011; Winter, 2016a). The basic task was innovated by Lynott and Connell (2009), who asked 55 native speakers of British English to rate a set of 423 property words (adjectives) on a scale from 0 to 5 on each of the five sensory modalities. The word yellow, for example, received an average rating of 4.9 on its “visual strength”, compared to ratings of 0, 0.2, 0.1 and 0.1 for tactile, auditory, gustatory and olfactory strength respectively. The norms can be considered “well-calibrated” with respect to studying the intersection of language and perception because they have been shown to correspond meaningfully to a number of behavioral measures (Connell & Lynott, 2010, 2012, 2014, 2016; Speed & Majid, 2017; van Dantzig et al., 2011) and linguistic patterns (Louwerse & Connell, 2011; Winter, 2016a, 2016b; Winter, Perlman, Perry, & Lupyan, 2017).

Here, we use the adjective norms collected by Lynott and Connell (2009) (N = 423), the noun norms by Lynott and Connell (2013) (N = 400) and the verb norms by Winter (2016a) (N = 300). Our total data set comprises 1123 words. For ease of discussion, we focus our analyses of token frequencies on the SUBTLEX corpus of movie subtitles (see Brysbaert & New, 2009 for arguments in favor of using this corpus). However, we replicate our analyses with several old and new frequency lists that are commonly used in psycholinguistics and linguistics (several are taken from the English Lexicon Project, Balota et al., 2007). These corpus-based word frequency lists include Kučera and Francis (Kučera & Francis, 1967), the Hyperspace Analogue of Language (HAL, Lund & Burgess, 1996), SUBTLEX-UK (Keuleers, Lacey, Rastle, & Brysbaert, 2012), CELEX (Baayen, Piepenbrock, & van Rijn, 1993) and the British National Corpus (Leech, 1992). These different corpora contain texts from multiple time spans and feature different linguistic registers and different dialects (both British English and American
English). For the register analysis, we additionally use the Corpus of Contemporary American English (COCA, Davies, 2005), which has 5 distinct linguistic registers: fiction, academic language, newspapers, magazines and spoken language. For the historical analysis, we used the Corpus of Historical American English (COHA).

2.2. Statistical analyses

All statistical analyses were performed within the R programming environment version 3.1.1 (R Core Team, 2016) and several R packages. In line with recommendations for reproducible research (Gentleman & Lang, 2007; Mesirov, 2010; Munafò et al., 2017; Peng, 2011), all data and analysis code is made publicly available and can be retrieved on GitHub: http://github.com/bodowinter/visual_dominance.

We performed two sets of analyses. In the first set of analyses, we used each word’s “dominant modality” (see Lynott & Connell, 2009), based on each word’s maximum perceptual strength rating. For example, the word yellow was classified as visual because its highest perceptual strength rating was for the visual modality, and the words rough and fragrant were classified as tactile and olfactory, respectively. In our categorical analyses, we focused on highly exclusive words, that is, words that were closely tied to a given modality. For this, we used Lynott and Connell’s (2009) measure of “modality exclusivity” (defined as the range of perceptual strength ratings divided by the sum of perceptual strength ratings), which measures the degree to which a word is relatively more multisensory (e.g., harsh is 11% exclusive) or unisensory (e.g., purple is 90% exclusive). In the second set of analyses, we used the continuous perceptual strength ratings. Here, words were allowed to be multisensory and their association with particular sensory modalities was a matter of degree rather than kind, e.g., the word yellow is relatively more visual than rough, which itself is relatively more visual than fragrant.

3. Results

3.1. Type frequencies

We first examined the visual dominance hypothesis by examining how many words are associated with vision, in contrast to the other sensory modalities. This has previously been examined in part by Lynott and Connell (2009, 2013) and Winter (2016b), but an integrated analysis is presented here to allow comparison with token frequencies. To compute discrete counts, we used the dominant modality classification. Fig. 1 shows the proportion of word types for each part-of-speech. For the property concepts from Lynott and Connell (2009), there are 205 visual adjectives (48%), 70 touch adjectives (17%), 68 sound adjectives (16%), 54 taste adjectives (13%) and 26 smell adjectives (6%). A chi-square test across these counts reveals they reliably deviate from a uniform distribution, $\chi^2(4) = 228.78$, $p < 0.0001$. The nouns from Lynott and Connell (2013) are also non-uniformly distributed, $\chi^2(4) = 1036.2$, $p < 0.0001$; with 336 sight-related nouns (84%), 42 sound-related nouns (10%), 14 touch-related nouns (4%), 6 taste-related nouns (2%) and 0 smell-related nouns (0%). Finally, the same applies to the verbs from Winter (2016a), $\chi^2(4) = 133.07$, $p < 0.0001$: there are 102 sight-related verbs (84%), 71 sound-related verbs (10%), 101

3.2. Token frequencies

Next, we examined whether each visual word is also used more frequently. An initial analysis revealed that there was an overall negative relationship between modality exclusivity and token frequency taken from SUBTLEX US (log estimate: $-0.7$, SE = 0.31, $p = 0.03$). Since the five sensory modalities systematically differ with respect to their modality exclusivity (Lynott & Connell, 2009, 2013), this could bias the analysis against more exclusive modalities. Moreover, when considering whether certain types of sensory experience are more likely to be verbalized, it is best to use words that are highly indicative of that sensory modality, i.e., words that have high modality exclusivity. Therefore, in the following analysis, we focused on the 10 most exclusive words per sensory modality per part-of-speech category. This resulted in a data set of 50 verbs, 50 adjectives, and 38 nouns (the unequal number comes from the fact that there are fewer than 10 nouns for taste and smell in the Lynott & Connell, 2013 dataset).
Descriptive averages for these highly exclusive words revealed that dominantly visual words were used on average 12,841 times each in SUBTLEX, followed by auditory words (5503 times), touch words (4653), taste words (1504), and smell words (939). The rank ordering for vision was the same regardless of whether one splits up these average counts for adjectives, verbs or nouns. So words that are (exclusively) highly visual were also used more frequently for all the part-of-speech categories considered in this study.

To model token counts inferentially, we regressed the raw counts from the SUBTLEX corpus onto the five different perceptual strength ratings (each rating scale was z-scored). We added parts-of-speech as a categorical control variable. Token counts were modeled using negative binomial regression, which is a form of the generalized linear model used for count data, similar to Poisson/loglinear models (for more details about this form of regression, see Zuur, Ieno, Walker, Saveliev, & Smith, 2009, and O’hara & Kotze, 2010). Just like Poisson models, the independent measure for this regression technique is counts (in this case, raw word frequencies), and the average rate of an event (in this case, the rate of a word occurring) is tied to the predictor variables via the log link function. In contrast to Poisson regression, negative binomial models include one additional parameter that estimates dispersion, which is desirable in the case of excess variance (“overdispersion”), a common characteristic of complex and highly variable linguistic data.

All five continuous perceptual strength measures were entered into the same model.2 The negative binomial regression model revealed a reliable positive effect on word token frequency only for visual strength ratings (log estimate: +0.66, SE = 0.18, p = 0.0002), and tactile strength ratings (+0.44, SE = 0.17, p = 0.009). There were no reliable effects for auditory strength ratings (+0.34, SE = 0.19, p = 0.076), gustatory strength ratings (−0.33, SE = 0.19, p = 0.076), or olfactory strength ratings (−0.37, SE = 0.21, p = 0.08). Fig. 2 shows the negative binomial regression coefficients for each sensory modality. All in all, we find words are more frequent if they correspond more strongly to visual content and tactile content, a tendency which is absent for sound, taste, and smell.

To test the generality of our results—i.e., to test whether the same pattern holds across words—we performed leave-one-out influence diagnostics for the two significant results reported above (i.e., visual and tactile strength ratings). For this, we re-fit the negative binomial regression model without the first word in the dataset, the second word etc. For visual strength ratings, the z-scored beta coefficients ranged from +0.56 to +0.76. There was no word exclusion that resulted in a non-significant result. For touch, the coefficients ranged from +0.30 to +0.56. If the word felt was excluded, the correlation between haptic strength ratings and frequency ceded to be statistically reliable (p = 0.07).

Finally, we assessed whether there was a distinct contribution of part-of-speech on the main result for vision. We fit another negative binomial regression model for just visual strength ratings, with an interaction term for parts-of-speech. This analysis revealed a reliable main effect of visual strength ratings, χ²(1) = 31.31, p < 0.0001, as well as a reliable interaction between visual strength ratings and parts-of-speech, χ²(2) = 9.55, p = 0.008. The frequency slope was strongest for adjectives (+1.43, SE = 0.26), with the noun (−1.17, SE = 0.44) and verb (−0.83, SE = 0.34) interaction terms adjusting this slope downwards, although not reversing, the main correlation between frequency and visual strength ratings.

Overall, then, these analyses show that visual words really are more frequent across the board than words from the other sensory modalities.

2 Because certain perceptual strength ratings are correlated with each other (such as taste and smell ratings, see Louvresse & Connell, 2011; Lynott & Connell, 2009), we assessed collinearity via variance inflation factors (see Zuur, Ieno, & Elphick, 2010). These were found to be low, indicating no problem with collinearity. Overdispersion tests indicated a significant degree of overdispersion, which justifies our choice of negative binomial regression models over Poisson models.

---

**Fig. 2.** Frequency coefficients from negative binomial model for associations between continuous perceptual strength ratings and SUBTLEX word tokens; error bars show 95% confidence intervals.

### 3.3. Stability of token frequencies

Next, we examined whether the patterns observed so far are a register-stable and time-stable property of the English language. Do our previous results generalize across different contexts of use? For ease of visualization, we use cumulative frequencies, which combine type counts and token counts, using the full datasets (across all parts of speech). This also gives a rough estimate of how much each sensory modality is talked about in relation to the others. Fig. 3 shows cumulative frequencies across seven different corpora of American English (SUBTLEX, COCA, HAL, Kučera-Francis) and British English (SUBTLEX-UK, CELEX, BNC). As can be seen, vision is consistently more frequent, regardless of the particular corpus or variety of English.

Separate negative binomial regression models were fitted to the frequencies from each corpus, with all five perceptual strength ratings treated as continuous predictors (z-scored). (Here again, we only use the 10 most exclusive words per sensory modality per part-of-speech.) There was a reliable positive association between frequency and visual strength ratings for all corpora (all p’s of visual strength coefficients < 0.001). The only other sensory modality for which perceptual strength ratings were reliably associated with frequency was the tactile modality (all p’s of tactile strength coefficients < 0.05); however, the association was consistently weaker than for vision. For vision, the largest z-scored coefficient was obtained for COCA (+1.09, SE = 0.23, p < 0.0001) and the smallest for Kučera-Francis (+0.59, SE = 0.13, p < 0.0001). For the same two corpora, the tactile modality had coefficients of only +0.77 (SE = 0.22, p = 0.0004) and +0.27 (SE = 0.13, p = 0.005), respectively. For the other sensory modalities, the only reliable effects were the following: in three out of the seven corpora, there was a statistically reliable positive association between auditory strength and word frequency (COCA: +0.50, SE = 0.25; HAL: +0.37, SE = 0.17; SUBTLEX UK: +0.40, SE = 0.19, all p’s < 0.05). In three out of the seven corpora, there was also a statistically reliable negative association between olfactory strength and word frequency (COCA: −0.92, SE = 0.27; HAL: −0.59; SE = 0.18; Kučera-Francis: −0.35, SE = 0.17). Gustatory strength did not correlate with frequency in any of the corpora (all p’s > 0.05).

Next, we assessed the generality of our results with respect to linguistic registers. We expected that certain linguistic registers differentially relate to particular sensory modalities. For example, taste and smell words have been shown to be used more often in emotional textual contexts (Winter, 2016a). Given this, it is possible that visual dominance might not hold across the board. Fig. 4 shows, however, that the pattern of visual dominance in cumulative frequencies is consistent across the five linguistic registers represented in the Corpus of Contemporary American English: academic language, fiction, magazines, news, and spoken language.

Separate negative binomial regression models were fitted to the
B. Winter et al.

reliable negative effects for visual (+0.34, SE = 0.07, p < 0.001) and auditory strength ratings (+0.45, SE = 0.07, p < 0.001), as well as a reliable negative effect for olfactory strength ratings (−0.4, SE = 0.1, p = 0.0001). So each of the five registers showed a reliable positive association between word frequencies and visual strength ratings. In addition, token frequencies displayed a reliable positive association for four out of the five registers for auditory strength ratings, and two registers for tactile strength ratings. On the other hand, token frequencies displayed a reliable negative association in two registers for gustatory strength ratings, and three for olfactory strength ratings. In sum, across different registers we find the same evidence of visual dominance.

Finally, we focused on the temporal dimension: is visual dominance a recent phenomenon or is it a time-stable property of the English language? Fig. 5 shows the frequency of sensory adjectives over 200 years of American English, with data taken from the Corpus of Historical American English (COHA). The plot shows descriptive means of relative frequencies. We computed relative frequencies because the total word count differs per decade. We computed the linear slope for each word and subjected these slopes as a dependent measure to a simple linear regression analysis with the single categorical predictor “modality”. Neither the total set of words, F(4, 1118) = 1.50, p = 0.2, nor the 10 most exclusive words per modality, F(4, 133) = 0.59, p = 0.67 showed a statistically reliable modality effect on the time-dependent frequency slopes. So, there is no substantial evidence for an overall increase or decrease in the relative frequency with which certain modalities are used across the last 200 years of American English.

This suggests a substantive degree of diachronic stability of the synchronic patterns we reported above.

4. Discussion

A number of studies demonstrate how the lexicon of English and other languages is optimized for communication about various conceptual domains, including color, ice and snow, and kinship (e.g., Gibson et al., 2017; Kemp & Regier, 2012; Regier et al., 2016). At the same time, a number of researchers have suggested that the English language? Fig. 5 shows the frequency of sensory adjectives over 200 years of American English, with data taken from the Corpus of Historical American English (COHA). The plot shows descriptive means of relative frequencies. We computed relative frequencies because the total word count differs per decade. We computed the linear slope for each word and subjected these slopes as a dependent measure to a simple linear regression analysis with the single categorical predictor “modality”. Neither the total set of words, F(4, 1118) = 1.50, p = 0.2, nor the 10 most exclusive words per modality, F(4, 133) = 0.59, p = 0.67 showed a statistically reliable modality effect on the time-dependent frequency slopes. So, there is no substantial evidence for an overall increase or decrease in the relative frequency with which certain modalities are used across the last 200 years of American English.

This suggests a substantive degree of diachronic stability of the synchronic patterns we reported above.

4. Discussion

A number of studies demonstrate how the lexicon of English and other languages is optimized for communication about various conceptual domains, including color, ice and snow, and kinship (e.g., Gibson et al., 2017; Kemp & Regier, 2012; Regier et al., 2016). At the same time, a number of researchers have suggested that the English language?
language, and other languages (e.g., Viberg, 1983; San Roque et al., 2015), exhibit visual dominance in usage and vocabulary structure. Here, we showed that the perceptual vocabulary of English strongly supports the visual dominance hypothesis—across parts-of-speech, registers, varieties of English, and across time. Vocabulary for concepts related to vision features more unique word types, and importantly, these words are also used more frequently. This suggests that precisely those perceptual domains that English speakers frequently talk about have greater expressive potential in terms of the structure of the vocabulary.4

The observed correspondence between type and token frequency is far from trivial. As an alternative baseline, if all other factors were equal, we would expect sensory domains with greater lexical differentiation to be less frequent because there are more visual words to choose from, thus lowering the average frequency of each word across this larger set of unique word types. That is, because English speakers have more visual words to choose from, the frequency of each individual word would be expected to be lower. Given this tradeoff, it is particularly noteworthy that despite a higher type frequency, we also found a higher token frequency for visual concepts.

Our general findings were supported by a series of statistical analyses of 1123 English words, including 423 adjectives, 400 nouns, and 300 verbs. Within this dataset, we found strong and consistent evidence of visual dominance, as well as for the diminished vocabulary and frequency for the sensory modalities of taste and smell. The long-held idea in linguistics that vision is the most differentiated sensory modality (see Levinson & Majid, 2014) was thus confirmed in a quantitative fashion, and in a way that generalizes beyond previous studies which have been limited to perception verbs and a few isolated word types (Viberg, 1983; Viberg, 1993; San Roque et al., 2015; but see Strik Lievers & Winter, 2018).

The fact that visual dominance in the lexicon—as well as the diminution of taste and smell—holds across nouns, verbs, and adjectives is particularly important. Although these grammatical categories are best defined distributionally (see Baker & Croft, 2017), each of these parts-of-speech is associated with particular semantic prototypes: time-varying events, processes and actions for verbs; time-stable objects and entities for nouns; and properties of intermediate temporal stability for adjectives (Givón, 1979, 2001 [1984]; Gärdenfors, 2014; Langacker, 2008; Murphy, 2010; Strik Lievers & Winter, 2018). Thus, nouns, verbs and adjectives serve quite different functions within a language, both morphosyntactically (their role within sentences), as well as semantically (the typical types of meaning they denote). Given this variability, it is particularly striking that vision is dominant for all lexical categories. Although Strik Lievers and Winter (2018) discuss some interesting relative differences in how the different sensory domains are expressed in particular parts-of-speech categories (in particular, auditory concepts are relatively more differentiated in the verbal domain), the results discussed here show a marked degree of visual dominance across the major parts-of-speech. This suggests that vision is more important regardless of whether one looks at property descriptions (adjectives), reference to objects (nouns) or descriptions of perceptual activities (verbs). The pattern of visual dominance in word frequencies was, however, strongest when looking at adjectives, arguably the class of words that is most directly about the content of sensory perception (e.g., blue, bright, murky, muddled).

Of course, it has to be noted that the register differences investigated in this study correspond to fairly coarse-grained differences in usage. The results we obtained here characterize large chunks of the English language, but they are compatible with other sensory modalities being relatively more important in more specialized discourse, such as cook books and movie reviews. Strik Lievers (2015) discusses Patrick Süskind’s novel The Perfume (Ger. Das Parfum) (see also Popova, 2003), and how in this particular novel, smell is the most frequent target domain of perceptual metaphors. Even if the visual dominance is reversed in particular specialist texts, the fact that we find visual dominance in large register-balanced corpora suggests that across-the-board, word frequencies exhibit visual dominance.

The flipside of the visual dominance we established with our English data is that some sensory modalities have diminished expressive capabilities and reduced frequencies. Our results fit particularly well with what has been said about smell, which has been characterized as a “muted sense” (Olofsson & Gottfried, 2015; Yeshurun & Sobel, 2010) due to its lack of lexical differentiation (see also Buck, 1949: chap. 15; Levinson & Majid, 2014), at least in many Western languages (cf. de Valk, Wnuk, Huisman, & Majid, 2017; Majid, 2015; Majid & Burenhult, 2014; Majid & Kruspe, 2018; O’Meara & Majid, 2016; Wnuk & Majid, 2014). We found fewer words were rated high on olfactory strength, and olfactory strength was negatively associated with word token frequencies, i.e., the more a word related to smell, the less frequent it was. Moreover, we found relatively few smell words to begin with. With respect to both type and token frequencies, taste behaved similarly to smell. This shows that although taste is important to speakers within certain domains (e.g., Korsmeyer, 1999)—as it is in importance compared to vision when taking into consideration language use in a broader context. The finding that taste and smell were both similarly infrequent fits the notion that these perceptual modalities are highly similar (Auvray & Spence, 2008; Rozin, 1982; Spence, Smith, & Auvray, 2015; Stevenson & Owen, 2010), and that their vocabularies are generally associated in language (Clasen, 1993, chap. 3; Louwverse & Connell, 2011; Winter, 2016a, 2016b).

A potential methodological concern arises from how the words were selected for the modality norming study. Clearly, the way a word list is chosen could impact the results. However, there are several reasons why sampling considerations cannot “explain away” the finding of visual dominance in English. First, the three word lists featured in this study were sampled in different ways: whereas Lynott and Connell (2009) was hand-compiled, Lynott and Connell (2013) was randomly assembled, and Winter’s (2016a) list contained a random (~40%) and a hand-compiled part (~60%). In addition, Strik Lievers (2015) hand compiled a list of words, and the results replicate there too (see Github repository). The fact that the same pattern of visual dominance was found across these different lists, shows this result is robust to type of sampling.

A pressing question is to what extent do the findings observed here generalize across cultures? It has been reported that certain cultures value smell relatively more, and correspondingly have more elaborated smell vocabularies (e.g., Burenhult & Majid, 2011; Majid & Burenhult, 2014; Majid & Kruspe, 2018; Wnuk & Majid, 2014). Majid et al. (in press) find that in terms of codability (i.e., consensus in how to describe sensory experiences) there is no universal hierarchy of the senses across a diverse set of unrelated languages. If a universal hierarchy is forced, then taste and color emerge as the most codable domains across languages, followed by shape, sound and touch, and finally, smell. This suggests that cultural factors can override the patterns we find for English here. However, it is also possible that the fit between type and token frequencies reported here is something that carries over to languages which have different rankings of the senses. This is something that requires systematic investigation.

To conclude, we found that asymmetries between the senses as revealed in perception, culture, and neuroanatomy correspond to asymmetries between the senses in the perceptual vocabulary of English, as well as to how this perceptual vocabulary is deployed in natural language use. In terms of both type and token frequencies, the senses are

4 The fact that the perceptual vocabulary is "optimized" (geared towards) communicative efficiency does not imply that it is in any ways "optimal", something which is difficult to measure and establish anyway (see Kimello & Marcus, 2009; Marcus & Davis, 2013, 2015). Instead, we view the patterns obtained here as broadly in line with usage-based theories of language which state that the structures of languages, including the structures of their lexicons, are shaped by communicative use (e.g., Barlow & Kemmer, 2000; Bybee & Hopper, 2001).
not created equal: there is demonstrable visual dominance in the usage of sensory words, as well as in the composition of the sensory lexicon. The finding that type and token frequencies are correlated supports the view that the perceptual vocabulary of English is oriented towards the needs of its speakers, with precisely those sensory domains more frequently verbalized also being the most lexically differentiated, allowing for more nuanced distinctions and more expressive descriptions of perceptual content. Our finding thus provides a prime example of how the composition of vocabularies of languages reflects communicative need.

Acknowledgments

We thank Jennifer Arnold and three reviewers (including Diane Pecher and Kyle Mahowald) for helpful comments. We thank Laurent Perek for his help with the COHA data. This work was funded in part by the Netherlands Organization for Scientific Research: NWO VICI grant “Human olfaction at the intersection of language, culture and biology”.
