Cytomatrix proteins CAST and ELKS regulate retinal photoreceptor development and maintenance

At the presynaptic active zone (AZ), the related cytomatrix proteins CAST and ELKS organize the presynaptic release machinery. While CAST is known to regulate AZ size and neurotransmitter release, the role of ELKS and the integral system of CAST/ELKS together is poorly understood. Here, we show that CAST and ELKS have both redundant and unique roles in coordinating synaptic development, function, and maintenance of retinal photoreceptor ribbon synapses. A CAST/ELKS double knockout (dKO) mouse showed high levels of ectopic synapses and reduced responses to visual stimulation. Ectopic formation was not observed in ELKS conditional KO but progressively increased with age in CAST KO mice with higher rates in the dKO. Presynaptic calcium influx was strongly reduced in rod photoreceptors of CAST KO and dKO mice. Three-dimensional scanning EM reconstructions showed structural abnormalities in rod triads of CAST KO and dKO. Remarkably, AAV-mediated acute ELKS deletion after synapse maturation induced neurodegeneration and loss of ribbon synapses. These results suggest that CAST and ELKS work in concert to promote retinal synapse formation, transmission, and maintenance.

Introduction

The presynaptic active zone (AZ) is a highly specialized subcellular compartment, where neurotransmitter-containing synaptic vesicles dock within a few tens of nanometers from voltage-gated calcium channels (CaV) and are prepared to fuse with the plasma membrane in a Ca2+-dependent manner. Synaptic signal transduction is coordinated by protein complexes at the pre- and post-synaptic sites. In this framework, the presynaptic release machinery is regulated by cytomatrix at the AZ (CAZ) proteins, including Munc13, RIM, Bassoon, CAST (also named ELKS2α or ERC2), and ELKS (ELKS1α or ERC1; Gundelfinger and Fejtova, 2012; Südhof, 2012; Ohtsuka, 2013) that compose the presynaptic density (Hagiwara et al., 2005). These proteins are believed to perform a variety of roles such as formation and maintenance of synapses, tethering and docking synaptic vesicles at AZ release sites, and recruitment of CaV channels to the AZ. In addition to studies investigating the functional properties of the individual CAZ proteins in various synapses (Südhof, 2012; Hamada and Ohtsuka, 2018), work using combinatorial deletion of proteins, such as ELKS (CAST/ELKS) and RIM, or RIM and RIM-BP, has shown a strong reduction of docked vesicles or presynaptic dense projections—classical morphological markers of the AZ (Acuna et al., 2016; Wang et al., 2016).

Elaborate electron-dense structures are found in invertebrate T-bar synapses and ribbon synapses of the vertebrate eye and ear (Zhai and Bellen, 2004; Wichmann and Moser, 2015; Maxeiner et al., 2016; Petzoldt et al., 2016). These so-called “synaptic ribbons” are mainly composed of RIBEYE and CAZ proteins, including Bassoon, Piccolo, RIM, and CAST (Schmitz et al., 2000; Dick et al., 2001; Khimich et al., 2005; Ohtsuka, 2013; Maxeiner et al., 2016; Jean et al., 2018). In this framework, genetic deletion of RIBEYE eliminated the ribbon and disrupted both fast and sustained neurotransmitter release from bipolar cells (BCs; Maxeiner et al., 2016). In contrast, in auditory hair cells, ribbon loss upon RIBEYE deletion led to elaborate developmental compensation that resulted in the formation of multiple ribbonless AZs at each synaptic contact with spiral ganglion neurons that sustained basic release rates (Becker et al., 2018; Jean et al., 2018). Bassoon, another multi-domain CAZ protein, exerts an essential role in anchoring the synaptic ribbon at the AZ membrane, and loss of Bassoon results in impaired transmission at retinal and cochlear synapses (Dick et al., 2003; Khimich et al., 2005; Buran et al., 2010). Deletion of RIM2 reduced Ca2+ influx and affected release from rod terminals without changing rod ribbon synapse anatomy (Grabner et al., 2015; Löchner et al., 2017). At hair cell...
synapses, RIM2 disruption reduced the number of presynaptic Ca\(^{2+}\) channels and tethered synaptic vesicles at the AZ membrane. Conversely, deletion of CAST, a molecular scaffold and protein interaction hub, reduced rod photoreceptor AZ size, ultimately leading to impaired electroretinogram (ERG) responses and attenuated contrast sensitivity (tom Dieck et al., 2012).

While the presynaptic function of CAST has been analyzed in various preparations over recent years (Takao-Rikitsu et al., 2004; Kaeser et al., 2009; tom Dieck et al., 2012; Held et al., 2016; Kobayashi et al., 2016), other work on invertebrate CAST/ELKS homologues in Caenorhabditis elegans (ELKS) and Drosophila melanogaster (bruchpilot) suggest additional roles in synapse formation and the promotion of AZ assembly, respectively (Dai et al., 2006; Kittel et al., 2006). In contrast, the role of presynaptic ELKS remains largely enigmatic, mainly owing to the fact that in vertebrates ELKS isoforms are ubiquitously expressed and constitutive ELKS knockout (KO) mice are embryonic-lethal (Deguchi-Tawarada et al., 2004; Liu et al., 2014). ELKS is characterized by higher solubility than CAST in spite of its 92% sequence similarity with the neuron-specific CAST (Ohtsuka et al., 2002; Fig. S1). Since ELKS is also found at retinal ribbon synapses (Deguchi-Tawarada et al., 2006), we hypothesized that ELKS may—at least partially—compensate for the loss of CAST from the synapse, thereby masking the individual contributions of CAST/ELKS family proteins in synaptic processes.

To elucidate the roles of ELKS and CAST in retinal photoreceptor AZ formation and maintenance as well as in synaptic processing of visual information, the present study established ELKS conditional KO (cKO) and CAST KO/ELKS cKO (double KO [dKO]) mice using a Crx-Cre line (Nishida et al., 2003) for retinal-specific deletion of ELKS. Comprehensive functional and anatomical analysis revealed that CAST and ELKS have both redundant and unique roles at the rod photoreceptor ribbon synapse. Remarkably, the acute deletion of ELKS from the mature retinal network induced a concomitant loss of ribbon synapses and photoreceptors. Therefore, we conclude that organization of release machinery with CAST and ELKS plays functional and anatomical roles in photoreceptor neurotransmission, the disruption of which may cause progressive blindness due to synaptic and neural remodeling.

## Results

### Combined ablation of ELKS and CAST from retinal photoreceptors causes impaired visual responses

First, we generated an ELKS cKO crossing ELKS\(^{lox/lox}\) mice with Crx-Cre mice for targeted deletion of exon 11 in the retina (Fig. 1A and Fig. S1; Nishida et al., 2003; Dong et al., 2018). Deletion of exon 11 causes a frameshift in exons 12 and 13, resulting in the premature termination of all ELKS isoforms including α, β, γ, δ, and ε (Fig. S1 C; Nakata et al., 2002), and hence elimination of all functional ELKS protein from the retina. ELKS cKO mice showed normal development, while mice carrying CAST\(^{-/-}\) and ELKS\(^{lox/lox}\) alleles as well as Crx-Cre (CAST/ELKS dKO) exhibited slightly smaller body weight and eye size (Fig. S2 A and Table S1). In accordance with a previous study (Deguchi-Tawarada et al., 2006), immunohistochemical analysis of ELKS expression in the retina confirmed the presence of ELKS in the outer plexiform layer (OPL), where rod and cone terminals form synapses with BCs and horizontal cells (HCs). In contrast, in the OPL of ELKS cKO mice, only a small number of nonspecific speckles could be observed (Fig. 1C). Similarly, the inner plexiform layer (IPL), containing the synapses formed by BC, amacrine, and ganglion cells, also showed ELKS immunofluorescence in control retinae that was absent in ELKS cKO mice (Fig. 1C). Immunoblotting of synapse-related proteins from retinal lysates confirmed the targeted deletion of ELKS and CAST in the respective individual KOs and the removal of both proteins from the dKO (Fig. 1, D and E). As previously reported (tom Dieck et al., 2012), we found a threefold, potentially compensatory up-regulation of ELKS in the CAST KO mice. Conversely, CAST expression increased in ELKS cKO mice (Fig. 1, D and E; and Fig. S2, B–E), indicating mutual compensatory up-regulation of both proteins. Interestingly, expression of RIM1/2, which directly interacts with CAST/ELKS (Ohtsuka et al., 2002; Wang et al., 2002; Deguchi-Tawarada et al., 2004), was decreased in the ELKS cKO and dKO mice, but not in the CAST KO mice (Fig. 1, D and E). We speculate that the reduction in RIM1/2 protein levels reflects the loss of an ELKS-RIM interaction, because the observed reduction of RIM1/2 was comparable between ELKS cKO and dKO mice (Fig. 1E) despite the prominent up-regulation of CAST in ELKS cKO mice.

To characterize visual function in mice of the different genotypes, we measured the ERG under scotopic conditions (Fig. 1, F–I). In these experiments, dark-adapted mice were exposed to dim light flashes of increasing intensity to trigger progressively stronger retinal responses. Here, the a-wave, indicating photoreceptor transduction, was unaltered across all genotypes. In contrast, the scotopic b-wave, reflecting rod photoreceptor transmission, was reduced in all mutants, from near normal in ELKS cKO to about half in the CAST KO mice, and nearly abolished in dKO. The oscillatory potentials, primarily reflecting the activity of the inner retina, were reduced in CAST KO and even further in dKO mice. Hence, the reduction in scotopic ERG signals indicates impaired synaptic transmission in the OPL and IPL in response to loss of CAST, a phenotype that is further aggravated by additional deletion of ELKS.

### Loss of photoreceptor ribbon synapses and enhanced formation of ectopic ribbon synapses

Next, we analyzed the formation of retinal layers. The thickness and the density of nuclei layers (outer nuclear layer [ONL] and inner nuclear layer [INL]) were not significantly different across the genotypes in the adult retina (~10 wk old; Fig. S2, F and G). In contrast, both CAST KO and dKO showed a reduction in OPL thickness (Fig. S2, F and G). In addition, dKO led to significant reduction in IPL thickness (Fig. S2, F and G), while the thicknesses of OPL and IPL were normal in the ELKS cKO. The reduced thickness of the synaptic layers suggests extensive remodeling of retinal synapses without major cell loss in the absence of CAST and ELKS.

The distribution of presynaptic proteins (i.e., RIBEYE and vGluT1) and synaptic connectivity with BCs and HCs was assessed by immunohistochemistry using cell type–specific markers (protein kinase C and calbindin, respectively; Fig. 2, A and B).
Both CAST KO and dKO mice exhibited an increase in the formation of ectopic ribbon synapses in the ONL, which were accompanied by abnormal sprouting of BCs and HCs dendritic processes (Fig. 2, A and B). Here, we quantified ectopically formed synapses in the ONL by measuring the displacement of RIBEYE-positive spots from the OPL to the ONL (Fig. 2 C). Immunolabeled ribbons were isolated from background noise by their fluorescent intensity and the spot size (see Materials and methods). While ~10% of synapses mislocalized to the ONL in the CAST KO, a staggering ~40% of synapses formed ectopically in the dKO (Fig. 2 C). Similar to the ribbon marker, the presynaptic terminal marker vGluT1 also exhibited ectopic synapse formation in CAST KO and dKO mice (Fig. S3 C). Age-related synaptic remodeling was apparent from the increase in ectopic synapse probability with advancing age in the dKO: ectopic synapses were identified as early as 5 wk of age and further increased up to...
progressive phenotype in CAST KO and dKO. Control, 5 wk (n = 3), 10 wk (n = 4), 40 wk (n = 4). CAST KO, 5 wk (n = 4), 10 wk (n = 6), 40 wk (n = 5), dKO, 5 wk (n = 4), 10 wk (n = 7), and 40 wk (n = 4). Colored asterisks indicate statistical significance from respective colored genotypes. *, P < 0.05; **, P < 0.01; ***, P < 0.001; ****, P < 0.0001 (two-way ANOVA followed by post hoc Bonferroni).
was significantly different between the genotypes (Tables S2 and S3). While we found BC tips to be comparable across all genotypes (Fig. 4D and Fig. S4), the majority of HCs only exhibited a single tip in CAST KO and dKO mice. In contrast, control and ELKS cKO mice always possessed at least two tips (Fig. 4E). Intriguingly, 3D reconstructions revealed that the single HC tip in the CAST KO and dKO mice branched before contacting the synaptic ribbon, forming a structure similar to that of the two HC tips that normally target the ribbon (Fig. 4B and Fig. S4). Although the individual tip sizes (surface area and volume) remained unaltered across all genotypes (Tables S2 and S3 and Fig. S4), the loss of the second HC tip from the triad of CAST KO and dKO retinae led to a significant reduction of the accumulated surface area and volume of HC tips (Fig. 4E, Fig. S4, and Tables S2 and S3). In CAST KO and dKO mice, overall HC counts, as measured by calbindin staining, remained unaltered (Table S5). However, 3D reconstructions of HC branching from a tip within a triad revealed fewer branches with filopodia-like structures that were lacking tips (Fig. S4E).

Photoreceptor ribbons have been proposed to play an important role in replenishing synaptic vesicles to the AZ (Jackman et al., 2009; Maxeiner et al., 2016). Hence, we next investigated synaptic ribbon morphology from 3D reconstructed images. In these experiments, reconstructed ribbons showed plate-like structures with a horseshoe-shaped appearance in the control and ELKS cKO (Fig. 4C). However, compared with control, ribbon lengths were significantly decreased in all deletion mutants, with the highest and comparable severity in CAST KO and dKO (Fig. 4G and Table S4). Moreover, we measured the shortest distance from the ribbon to the surface of BC tips, and found it to be
significantly longer in the dKO compared with control (Fig. 4 H). The CAST KO fell in between, showing no statistical difference in ribbon–BC tip separation for the CAST KO versus dKO, nor the CAST KO versus control.

Overall, the 3D reconstructions of FIB-SEM data revealed impaired triad formation that can be summarized as follows for the CAST KO and dKO: (a) reduced HC branching, (b) decreased surface area of the HC processes in the rod triads, (c) diminution of ribbon size (and to a lesser extent in ELKS cKO), and (d) increased width of the synaptic cleft between rod ribbons and BC tips. In other words, CAST and ELKS codetermine the structure of the rod ribbon synapses and synaptic connectivity with HCs and BCs (Fig. 4 I), with CAST exerting a more prominent role than ELKS. Combining these findings with conventional EM, the rod AZs of CAST KO and dKO mice are similar in many ways: both show truncated ribbons and comparable vesicle density. The increased distance from the ribbon to the BC tips might not suffice to explain the severely attenuated scotopic b-waves and the enhanced formation of ectopic synapses in the dKO. Although ELKS itself seems to contribute in a minor way to the presynaptic...
morphology, it may affect AZ function. Therefore, we next probed rod Ca\textsubscript{v} channels to assess if their function behaves differently in the CAST KO and dKO.

**Roles of CAST and ELKS in the voltage-dependent calcium influx at rod terminals**

L-type Ca\textsubscript{v}1.4 channels localize to rod ribbon synapses (Liu et al., 2013; Zabouri and Haverkamp, 2013), and previous work suggests that its pore-forming α1 subunit (tom Dieck et al., 2012) and α2δ4 auxiliary subunit (Wang et al., 2017) traffic to the downsized ribbons formed by CAST KO rods. Therefore, we performed whole-cell voltage-clamp recordings from rods to test the behavior of the Ca\textsubscript{v}1.4 channels in acute retinal slices from adult control, CAST KO, and dKO mice (4 mo of age). Calcium currents (I\textsubscript{Ca}) were recorded from rod somata located on the ONL border to the OPL, where the synaptic ribbon is contained in the soma compartment (Fig. 5 A; Grabner et al., 2015). While the example control recording showed an inward I\textsubscript{Ca} with a peak amplitude of approximately −9 pA when the voltage was ramped from −70 to +50 mV, the response acquired from a CAST KO was essentially flat (Fig. 5, B and C). To illustrate the excitability of cells without I\textsubscript{Ca}, the cells were also given steps from −70 to −90 mV to activate the hyperpolarizing inward current (I\textsubscript{h}) carried by hyperpolarizaton-activated cyclic nucleotide-gated channels (Bader et al., 1982). The hyperpolarizing voltage step followed by a depolarizing voltage ramp activated an I\textsubscript{h} current in rods (Fig. 5 D), but I\textsubscript{Ca} was seldom detected in CAST KO and dKO mice. In addition, rod somata located in the ONL (about a single row of soma away from the OPL) were also patched, thus allowing the visualization of the rod’s short axon linked to the small terminal (Fig. S5 A). Again, the I\textsubscript{Ca} was either strongly reduced or almost absent in CAST KO and dKO mice, while I\textsubscript{h} currents as well as an outward current related to the inner segment (Barnes, 1994; Grabner et al., 2015) were routinely observed (Fig. S5, B and C). The summarized data show a drastically reduced I\textsubscript{Ca} in CAST KO and dKO relative to control, while the KO mice were not significantly different from one another (Fig. 5 F and Fig. S5 G). In addition, we estimated the voltage where the I\textsubscript{Ca} reaches half maximal amplitude on the voltage ramp (V\textsubscript{1/2}) in recordings with measurable I\textsubscript{Ca}, which can indicate modulation of Cav gating. The V\textsubscript{1/2} values were similar across the genotypes: control = −29 ± 1.5 mV (n = 9 cells), CAST KO = −30 ± 1.4 mV (n = 4 cells), and dKO = −31 ± 1.9 mV (n = 7 cells). However, it should be noted that only half of CAST KO (four of eight cells) and dKO (7 of 16 cells) had sufficient I\textsubscript{Ca} amplitudes (>0.5 pA) to estimate the V\textsubscript{1/2}. These results indicate that CAST plays an essential role in maintaining Ca\textsuperscript{2+} entry into rod terminals.

**Acute deletion of ELKS induces photoreceptor remodeling and elimination of ribbon synapses**

ELKS is ubiquitously expressed, including in nonneural tissues, and constitutive ELKS KO is embryonic-lethal (Deguchi-Tawarada et al., 2004; Liu et al., 2014). Therefore, developmental compensation by other presynaptic terminal proteins might mask the ELKS KO phenotype in our preparation. To address this issue, we next investigated ELKS function in photoreceptors after intact synapse formation and maturation. In these experiments, acute ELKS deletion was achieved by intravitreal injection of adeno-associated virus serotype 5 (AAV5) encoding Cre (AAV5-CAGGS-nCre) into ~5-wk-old ELKS\textsuperscript{f/f} animals. At 3 wk after injection, robust Cre recombinase expression was observed in photoreceptors (Cre-positive; Fig. 6 and Fig. S6). Acute ELKS cKO induced a reduction in ONL thickness, suggesting substantial photoreceptor loss (Fig. 6). Ribbon synapse density in the OPL (as assessed by RIBEYE immunolabeling) decreased by 64% in the Cre-positive region compared with the proximal Cre-negative regions (Fig. 6, B, D, and F). The acute depletion of ELKS in CAST KO retinae led to partial ablation of the ONL, as illustrated by an almost complete loss of ribbon synapses, i.e., 89% (Fig. 6 D and Fig. S5). Moreover, we have confirmed
that acute ablation of ELKS by AAV-Cre expression caused loss of ELKS protein at the OPL in ELKS<sup>fl/fl</sup> mice (Fig. 7 A), which difference was even more drastic in CAST KO ELKS<sup>fl/fl</sup> mice (Fig. 6 G). Because ELKS expression was up-regulated in the CAST KO retina (Fig. 1 D), acute dKO after synapse formation might induce photoreceptor degeneration more severely than acute ELKS cKO. To establish whether these effects were indeed a direct result of ELKS elimination from photoreceptors and exclude adverse effects due to the virus application, we also injected AAV5-CAGGS-nCre into ELKS<sup>fl/fl</sup> x Crx-Cre<sup>+/−</sup> (ELKS cKO) mice. Importantly, acute Cre expression in ELKS<sup>fl/fl</sup> x Crx-Cre<sup>−/−</sup> (ELKS cKO) mice affects neither ONL thickness nor RIBEYE density, indicating a CAST/ELKS-dependent mechanism as the underlying cause; mean ± SEM. ONL: ELKS<sup>fl/fl</sup> Cre (n = 5 mice), Venus (n = 2), ELKS<sup>fl/fl</sup> x Crx-Cre<sup>−/−</sup>; Cre (n = 3), Venus (n = 3), CAST KO; ELKS<sup>fl/fl</sup> Cre (n = 3), and Venus (n = 3), RIBEYE: ELKS<sup>fl/fl</sup> Cre (n = 5), Venus (n = 2), ELKS<sup>fl/fl</sup> x Crx-Cre<sup>−/−</sup>; Cre (n = 3), Venus (n = 2), CAST KO; ELKS<sup>fl/fl</sup> Cre (n = 4), and Venus (n = 3). *, P < 0.05; **, P < 0.01 (two-sided Student’s t test). 

(G) Ablation of ELKS in the OPL in CAST KO; ELKS<sup>fl/fl</sup> Cre (+) retina (arrows). Bar, 50 µm.
IRES-Venus in cultured neurons, in which CAST was strongly expressed in Venus-positive neurons (Fig. S6, F and G).

The acute depletion of ELKS in retinae lacking CAST led to partial ablation of the ONL, as illustrated by an almost complete loss of ribbon synapses (Fig. 6, D and F). Hence, acute ablation of ELKS after synapse formation might induce photoreceptor degeneration more severely in the absence of CAST, indicating overlapping roles between ELKS and CAST, as suspected from the observed compensatory up-regulation of ELKS expression in CAST KO retinae (Fig. 1 D and Fig. 6 G).

Discussion

Photoreceptors transform light into membrane voltages, which in turn drives signal transmission to the inner retina. The molecular physiology of synaptic transmission at rod photoreceptors remains incompletely understood. In the current study, we analyzed structural and functional changes in the retina upon deletion of the highly homologous multi-domain proteins of the AZ, CAST, and ELKS. This study revealed that both CAST KO and CAST/ELKS dKO rod terminals exhibited altered triad ribbons and HC processes, drastically reduced calcium influx and comparable loss of synaptic ribbons from the OPL, and, finally, exhibited extensive synaptic remodeling involving ectopic synapses in the ONL. In addition, rod ribbon synapses of the dKO exhibited fewer ribbon-associated synaptic vesicles and a greater separation of the ribbon from the BC dendrite. Moreover, dKO mice exhibited the largest number of ectopic ribbon synapses in the ONL. Taken together, these additional deficits are likely to account for the stronger reduction in the scotopic ERG b-wave in dKO mice, compared with that observed in the CAST KO mice. In contrast to CAST, ablation of ELKS early in development did not
significantly alter ERG responses or ribbon anatomy. However, ELKS deletion after synapse formation caused massive loss of ribbon synapses and photoreceptors, which was partially halted by CAST. In summary, our data indicate that CAST and ELKS are critical for visual processing by exhibiting both redundant and complementary functions in synapse formation, function and maintenance in retinal rod photoreceptors.

A role for CAST/ELKS in presynaptic Ca$^{2+}$ influx
Using whole-cell voltage-clamp recording from rod photoreceptors (Grabner et al., 2015; Wang et al., 2017), which gives unprecedented access to a synaptic ribbon, we demonstrated that CAST elimination greatly reduces the Ca$^{2+}$ influx via CaV channels. This finding is consistent with previous studies in which CAST deletion not only decreases ribbon lateral expansion but also reduces presynaptic Ca$_{V}$1.4 abundance at rod AZ (tom Dieck et al., 2012; Wang et al., 2017). Interestingly, RIM2, which interacts with CAST (Wang et al., 2002) and is located at rod ribbons near Ca$_{V}$1.4 channels, also promotes Ca$^{2+}$ influx into mouse rods (Grabner et al., 2015). A role of CAST/ELKS in regulating presynaptic Ca$^{2+}$ influx has also been reported in cultured hippocampal neurons. One previous study reported that action potential-driven changes in Ca$^{2+}$ levels at the nerve terminals were lower than in control mice despite apparently normal expression of Ca$_{V}$ channels (Liu et al., 2014). In accord with this finding, another study reported a direct interaction of CAST with Ca$_{V}$ α1 and β subunits, and further reported a CAST-dependent hyperpolarizing shift in the voltage dependence of presynaptic Ca$^{2+}$ channels upon coexpression in a heterologous expression system (Kiyonaka et al., 2012). Loss of CAST from rods greatly reduced the magnitude of Ca$^{2+}$ currents. Taken together, these results suggest that CAST directly or indirectly regulates Ca$_{V}$ abundance and function.

Morphological abnormalities of rod synapses in CAST KO and dKO mice
The impact of the loss of CAST/ELKS on the molecular architecture of rod triads was investigated by 3D reconstruction from a set of serial images using FIB-SEM (Kitahara et al., 2016). In these experiments, we observed varying degrees of ribbon size reduction in all deletion mutants (Fig. 4), consistent with a previously proposed scaffolding role of CAST/ELKS that facilitates the lateral expansion and structural integrity of retinal ribbons (tom Dieck et al., 2012). Interestingly, neither the limited reduction of ribbon size (<30%) nor the observed lateral fragmentation of ribbon bodies (Table S4) significantly affected photoreceptor neurotransmission or ERG performance in ELKS cKO mice (Fig. 1, F–I). In contrast, the major reduction in ribbon length of ∼50–70% in CAST KO and dKO mice severely impaired synaptic function and visual processing.

According to the 3D reconstruction of the rod terminal, a single HC tip triad was formed in the CAST KO and dKO mice (Fig. 4). Further 3D reconstruction of the HC tips revealed fewer branches and the occurrence of filopodia-like structures (Fig. S4 E). We assumed an HC morphological impairment caused by the absence of CAST in HCs, mostly because Crx-driven Cre recombinase could eliminate ELKS only in non-HC neurons in the INL (Fig. S4, F–H). Therefore, the phenotypes seen in HCs could be explained by the cell-type–independent depletion of CAST in CAST KO and dKO mice. In this context, CAST localization at the growth cone was previously suggested to play a role in maturation of neural circuits in primary cultured neurons (Ohnaka et al., 2002). Previous reports also showed comparable single HC tip morphology in deletion mutants of PlexinA4 and netrin-G ligand 2, which are selectively localized to HC neurites and tips, respectively (Matsuoka et al., 2012; Soto et al., 2013; D’Orazi et al., 2014).

Enhanced ectopic synapse formation in retinale CAST/ELKS deletion mutants
We previously found that retinale of CAST KO exhibited ectopic ribbons (tom Dieck et al., 2012). In the current study, we found that the compound deletion of ELKS and CAST further confounded synapse stability. Several previous studies have shown that mutation or deletion of various proteins involved in synaptic transmission was associated with ectopic ribbon formation (Dick et al., 2003; Schmitz et al., 2006; Specht et al., 2007; Maxeiner et al., 2016). As an extreme example, depletion of synaptic vesicle protein cystein string protein α causes ectopic synapse formation in concert with massive photoreceptor degeneration (Schmitz et al., 2006). Bassoon is a prominent example of an AZ protein, which is essential for anchoring the photoreceptor ribbon to the AZ, and its deletion is associated with ectopic synapses (Dick et al., 2003). Moreover, mouse models of congenital stationary night blindness that carry mutations in the Ca$^{2+}$ channels and/or its binding proteins are in accord with hypothesized causal relationship between loss of AZ structural as well as functional integrity and ectopic synapse formation (Haeseeler et al., 2004; Chang et al., 2006; Liu et al., 2013; Regus-Leidig et al., 2014).

Thus, current data from CAST KO and dKO mice confirmed that impairment of neurotransmission drove ectopic synapse formation in the ONL, which was exacerbated with aging in CAST KO and dKO mice.

Synaptopathies and retinal degenerative disease
The remodeling of photoreceptors is a hallmark of various acquired retinal diseases, such as retinitis pigmentosa (RP), which is mostly classified as inherited retinal dystrophy. The progression of RP is variable, although continued photoreceptor degeneration ultimately leads to functional blindness (Kalloniatis et al., 2015). Although several gene mutations have been identified from severe RP forms (Ferrari et al., 2011), and gene therapeutic approaches are currently under development (Zarbin, 2016), the precise molecular mechanisms of RP progression are not well understood. Recent advances in stem cell therapy hold great promise for the treatment of advanced RP by transplantation of embryonic and induced pluripotent stem cells (Shirai et al., 2016; Zarbin, 2016). Nevertheless, it is of utmost importance to suppress disease progression and retain normal vision for as long as possible. Thus, it is important to (a) understand the factors that initiate and facilitate neural remodeling and (b) identify molecular targets that are amenable to genetic therapy. In the current study, we found that the loss of ELKS in mature ribbon synapses induces photoreceptor degeneration, which was not apparent in the Cre-mediated ELKS cKO model, suggesting a novel molecular mechanism that specifically induces photoreceptor remodeling.
and degeneration (Fig. 7, G and H). Thus, to develop novel therapies for late-onset retinal neurodegenerative disease, future studies should (a) identify potential relationships between RP mutant genes and AZ proteins and (b) analyze functional roles of RP mutant genes in neurotransmitter release.

**Materials and methods**

**Generation of ELKS cKO mice**

The use of the animals was approved by the Institutional Committee for the Care and Use of Experimental Animals at the University of Yamanashi, Yamanashi, Japan.

Inducible retina-specific ELKS mutant mice were obtained by crossing ELKS\(^{\text{flox/flox}}\) mice (Dong et al., 2018) with Crx-Cre mice carrying Cre recombinase under control of the Crx promoter, which is an otx-like homeobox gene expressed abundantly in the retina (provided by T. Furukawa, Osaka University, Osaka, Japan; Nishida et al., 2003). The ELKS\(^{\text{flox/flox}}\) mice were further crossed with CAST\(^{-/-}\) (tom Dieck et al., 2012) to generate CAST\(^{-/-}\); ELKS\(^{\text{flox/flox}}\) mice. The mice derived from crossing ELKS\(^{\text{flox/flox}}\) mice with ELKS\(^{\text{flox/flox}}\); Crx-Cre\(^{+/+}\) mice and CAST\(^{-/-}\); ELKS\(^{\text{flox/flox}}\) with CAST\(^{-/-}\); ELKS\(^{\text{flox/flox}}\); Crx-Cre\(^{+/+}\) mice and CAST\(^{-/-}\); ELKS\(^{\text{flox/flox}}\) with CAST\(^{-/-}\) were used for subsequent studies. Genotyping of ELKS cKO, CAST KO, and dKO mice by PCR was performed using the following primers: ELKS flox forward, 5′-AAG

\[\text{GCT GCG TAT GGC GTC TGG GCA-3′}.\]

ELKS flox reverse, 5′-TCG CAC TGA TGG AAG GTC CAC-3′, mLC3ex3GT-Cre3, 5′-TGA

\[\text{AGT TGG TCT TCC AAC ATG CTC-3′};\]

**Immunoblotting**

Retina homogenates from the adult mutant mice were analyzed using Western blotting, and the signal intensity was quantified using ImageJ software (National Institutes of Health) from more than three independent experiments. The primary antibodies used for Western blotting were anti-ELKS (1:500, rabbit; Ohtsuka et al., 2002), anti-RIM1/2 (1:1,000, rabbit; provided by S. Miyazaki, Kyoto University, Kyoto, Japan; Kiyonaka et al., 2007; Kiyonaka, Kyoto University, Kyoto, Japan; Kiyonaka et al., 2007; Kiyonaka et al., 2007; Kiyonaka et al., 2007), anti-RIM1/2 (1:1,000, rabbit; 192003; SYSY), anti-synaptophysin (1:2,000, mouse; C9848; Sigma-Aldrich), and anti-Cre (1:800, mouse; ab31; Abcam), anti-vGluT1 (1:1,000, guinea pig), anti-calbindin (1:2,000, mouse; C9848; Sigma-Aldrich), and anti-Cre (1:800, mouse; MAB3120; and 1:500, rabbit; 69050-3; Millipore). A guinea pig antiserum against vGluT1 was raised against mouse vGluT1 C-terminal 531-560 aa (NM020309; Miyazaki et al., 2003). The sections were further processed with appropriate Alexa Fluor-conjugated secondary antibodies for 1 h at room temperature. Immunolabeled samples were viewed using a confocal laser microscope (FV1200; Olympus) at room temperature.

**Distribution of ribbon synapses**

RIBEYE-immunoreactive images were obtained with oil-immersion 60× objective (NA 1.35) with 2× digital zoom, and then binary-transformed (threshold ~1,300) images were analyzed using the ImageJ particle analysis program (particles smaller than 20 pixels were eliminated; Fig. S3). The total number of particles in OPL and ONL were divided by the area to calculate the RIBEYE density. The distance of each particle from the bottom of the OPL (y axis) was evaluated by generating histograms and plotted as the cumulative frequency (%) for display. The statistical significance of density and probability for each distance from OPL and ONL were analyzed by one-way ANOVA or two-way ANOVA, respectively.

**Imaging with FIB-SEM and 3D reconstruction**

The mice were transcardially perfused with 2% glutaraldehyde and 2% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4). Retinal sections (thickness, 400 µm) were further en bloc stained with a reduced OTO staining method: 1.5% potassium ferrocyanide, 2% OsO\(_4\), 1% thiocarbohydrazide, and then 2% OsO\(_4\). For counterstaining, sections were further treated with 4% uranyl acetate and Walton’s lead aspartate solution. After staining, samples were dehydrated and embedded in epoxy resin (EPON812; TAAB). Specimens were subjected to FIB-SEM tomography (Quanta 3D FEG; FEI) as previously described (Kitahara et al., 2016). In brief, the embedded slices were placed on a metal stub and further trimmed with glass and diamond knives in an ultramicrotome (Ultracut E microtome; Leica). The slices were coated with an electroconductive layer of carbon, which prevented any charge. The metal stub with the slices was set on the FIB-SEM stage, and then serial section images were automatically obtained from the OPL of the retina. Serial images of the block face were acquired by repeated cycles of sample surface milling and imaging using the Slice & View G2 operating software (FEI). The milling was performed with a gallium ion beam at 30 kV with a current of 1.0 nA. The milling pitch was set to 15 nm/step. The images were acquired at an accelerating voltage of 2.5 kV. The other acquisition parameters were as follows: dwell time = 6 s/pixel and pixel size = 7.3 nm/pixel. The serial section images were reconstructed to 3D images and analyzed using Amira 5.5 software (FEI).
**ERG recordings**

Mice were adapted to the dark overnight and anesthetized by intraperitoneal injection of ketamine (0.125 mg/g) and xylazine (2.5 μg/g), and one pupil was dilated with 1% atropine sulfate. All preparations were done under a dim red light. A ring-like AgCl wire electrode, moistened by methylcellulose and NaCl solutions, was placed on the cornea, and a needle reference electrode was subcutaneously inserted above the nose with a ground electrode near the tail. A custom-designed Ganzfield illuminated by 25 white LEDs was used to produce light flashes of incremental luminances (0.0003 to 0.278 candela/m²; measured by Mavolux, IPL 10530). Scotopic responses were recorded for a stimulus duration of 0.1 ms with an inter-stimulus interval of 5 s. Recorded potentials were amplified, filtered (<400 Hz for a-waves, <20 Hz for b-waves, and 30–400 Hz for oscillatory potentials), and sampled at a rate of 24 kHz. 10 responses were averaged per light intensity. For analysis, a-wave amplitudes were measured relative to the baseline, whereas b-wave amplitudes were estimated relative to the trough of the a-wave. All data were analyzed using custom-written MATLAB-based analysis routines. Statistical significance was assessed by repeated measures two-way ANOVA followed by post hoc Tukey corrected for multiple comparisons.

**Loan cell voltage clamp recording**

Mice between 14 and 18 wk of age were tested. Preparation of retinal slices and whole-cell voltage clamp recordings were conducted as described previously (Grabner et al., 2015). Briefly, retinal slices (~200 μm thickness) were prepared in the following mouse extracellular solution, which had a low Ca²⁺ concentration (in mM): 135 NaCl, 2.5 KCl, 0.5 CaCL₂, 1 MgCl₂, 10 glucose, and 15 Hepes, pH 7.35, with osmolarity adjusted to 295 mOsm. Slices in the recording chamber were then continually perfused in mouse extracellular solution with 2.5 mM Ca²⁺ at a temperature of 30°C to 32°C. The intracellular solution contained the following reagents (in mM): 105 CsCH₃SO₄, 20 TEA-Cl, 2 MgCl₂, 5 MgATP, 0.2 NaGTP, 10 Hepes, 10 EGTA, and 10 μg/ml Alexa Fluor 488, with pH adjusted to 7.30 with CsOH to an osmolarity of 285 to 290 mOsm. The theoretical junction potential generated with these intra- and extracellular solutions is estimated to be ~12 mV. The voltage-clamp data are not presented with the ~12 mV added (V₁/₂ and current traces plotted over voltage are raw values). The hyperpolarizing Iₒ current was monitored to confirm the intactness of the recording.

The ramp protocols were preceded by steps from ~60 to ~70 mV or ~70 to ~90 mV (to activate Iₒ), and then ramped to ~50 mV at a speed of 1 V/s. Since these two ramp types gave very similar Iₒ and V₁/₂ values within cells, data were summarized by averaging together the different voltage ramps. Average values from five control cells for ramps starting at ~70 and ~90 mV were as follows: Iₒ, 12.1 vs 11.8 pA (P = 0.95), and V₁/₂, −28 vs −30 mV (P = 0.61).

**Statistical analysis**

Data are presented as mean ± SEM. Data distribution was assumed to be normal, but this was not formally tested. Statistical significance was analyzed using one-way ANOVA, two-way ANOVA, or two-sided Student’s t test as indicated in each figure legend and in Table S6.

**Online supplemental material**

Fig. S1 shows the details of ELKS cKO with amino acid sequence of CAST and ELKS and their different solubility. Fig. S2 and Table S1 show the characterization of each genotype of mice including three Cre or Venus expression images (Cre[+], Venus[+]) and non-Cre or -Venus expression images (Cre[−], Venus[−]) from the same retina. For ONL thickness, the images were obtained using a 40× objective lens (NA 0.95). RIBEYE density was calculated from images taken with a 60× objective and a 2× digital zoom. ONL thickness and RIBEYE densities were analyzed using ImageJ and compared between Cre-positive and -negative regions using the Student’s t test.
body weight and eyeball size, original data of immunoblotting, and retinal layer formation. Fig. S3 shows the analysis of ectopic ribbon synapse immunolabeled with RIBEYE and vGluT1. Fig. S4 and Tables S2, S3, and S4 give the additional data from the 3D-reconstructed rod terminal from each genotype of mice. Fig. S4 demonstrates lower expression of Cre recombinase in HC and Table S5 shows the line density of HC was not significantly different between genotypes. Fig. S5 shows the recording of Ca2+ current from rod photoreceptors with inner segments. Though the traces of Ca2+ current with inner segments showed outward current, the peak amplitude and V1/2 were not significantly different from the soma without inner segments. Then the data were pooled and statistically analyzed between genotypes. Fig. S6 shows the AAV-mediated Cre and Venus expression in ELKS cKO (ELKS0/0 x Crx-Cre−/+), and CAST KO; ELKS0/0 mice. Fig. S6, G and H, also showed the AAV-mediated expression of CAST and Venus in primary culture neurons for rescue experiments. Table S6 shows summary of statistical analysis.

Acknowledgments

We thank N. Sugiyana, K. Moriya, and all members of the Ohtsuka Laboratory for their helpful discussions and technical assistance, and S. Thom for expert technical assistance with the ERG recordings. We also thank Dr. T. Furukawa for the Crx-Cre mouse and Dr. S. Kyonaka for the RIM antibody.

This work was supported by Japan Society for the Promotion of Science KAKENHI grants 25830008 (to A. Hagiwara), 15H04272 (to T. Ohtsuka), and 16H05135 (to A. Nishi); a Grant-in-Aid for Scientific Research on Innovation Area “Dynamic Regulation of Brain Function by Scrap and Build System” from the Ministry of Education, Culture, Sports, Science and Technology, grant 17H05741 (to T. Ohtsuka); Japan Science and Technology Agency CREST, grant JP17MJCr1751 (to T. Ohtsuka); and the University of Yamashaki. Work on the Göttingen Campus was supported by the German Research Foundation through Collaborative Research Center 889 (to T. Moser) and the Max Planck Society (fellowship to T. Moser). C. Vogl is a Creutzfeldt Fellow of the Elisabeth and Helmut Uhl Foundation. Production of AAV vectors was supported by the Cooperative Study Program of the National Institute for Physiological Sciences (K. Kobayashi).

The authors declare no competing financial interests.

Author contributions: A. Hagiwara designed and performed the biochemical, morphological, and optical imaging analysis, with the support of R. Kitta, and drafted the manuscript. T. Ohtsuka directed the study and edited the manuscript. Y. Kitahara, K. Ohta, K. Nakamura, and A. Nishi performed FIB-SEM and 3D reconstruction analysis. C. Vogl and T. Moser performed physiological analysis and edited the manuscript. C.P. Grabner performed and analyzed the whole-cell recordings and edited the manuscript. M. Abe and K. Sakimura generated the ELKS floxed mouse. All authors read and approved the final manuscript.
