(Dated: May 13, 2022)

We establish a general framework for studying the bound states and the photon-emission dynamics of quantum emitters coupled to structured nanophotonic lattices with engineered dissipation (loss). In the single-excitation sector, the system can be described exactly by a non-Hermitian formalism. We have pointed out in the accompanying letter [Gong et al., arXiv:2205.05479] that a single emitter coupled to a one-dimensional non-Hermitian lattice may already exhibit anomalous behaviors without Hermitian counterparts. Here we provide further detail on these observations. We also present several additional examples on the cases with multiple quantum emitters or in higher dimensions. Our work unveils the tip of the iceberg of the rich non-Hermitian phenomena in dissipative nanophotonic systems.

I. INTRODUCTION

Controlling the interaction between atoms (few-level systems) and light (bosonic fields) is a central goal in quantum optics. Recently, there has been considerable interest in controlling the propagation of light, and thus its interaction with atoms, through nanophotonic structures or atomic arrays [1]. In addition, there are longstanding efforts to create synthetic quantum optical systems comprised of artificial atoms coupled to arrays of bosonic modes, for example transmon qubits coupled to superconducting circuits [2–5] or surface acoustic waves [6], or ultracold atoms in state-dependent lattices [7–9]. Engineering the bath has the potential of dramatically improving key figures of merit, such as storage fidelity [10], or to enable novel devices, for example to simulate spin systems with long-range interactions [11] or interactions with exotic spatial profiles [12]. These successes motivate the search for other design paradigms, with novel physics, that may be exploited in future devices.

In a different context, there is remarkable recent progress on understanding non-Hermitian (NH) systems [13–16], which may exhibit peculiar properties without Hermitian counterparts [17–35]. One of the most well-known unique features is exceptional points (EPs), which are specific points in the parameter space where the NH Hamiltonian becomes non-diagonalizable and some of its eigenstates coalesce [36]. In lattice systems, the parameter space is typically the Brillouin zone and an EP may appear at a band touching point. Depending on the symmetry of the Hamiltonian and the dimension of parameter space, the EPs may form curves, surfaces or even higher-dimensional objects [37–39]. More recently, the NH skin effect [30], which refers to the phenomenon where the “bulk” eigenstates of a NH lattice localize at the boundary under open boundary conditions (OBCs), has attracted considerable interest. In one dimension (1D), the skin effect has been found to originate from the point-gap topology and may be enriched by symmetries [40, 41]. In higher dimensions, the skin effect has been shown to appear as long as the energy spectrum covers areas rather than curves [42], which is typically the case. Some unique NH phenomena have been observed in various experimental platforms, including but not restricted to mechanical [43–48], optical or photonic [49–60], atomic [61–64], and electric or superconducting circuit [65–67] systems

In this work, we merge these two emergent fields by studying quantum emitters in NH baths in a relatively comprehensive manner. While there are a few previous studies about this topic (see, e.g., Refs. [68, 69]), all of them focus on rather specific (classes of) models. Moreover, the role of genuine NH topology [31, 34, 35] remains fully unexplored. Here, we establish a general framework encompassing all the related previous works. We restrict ourselves to the single-excitation sector, for which the NH description becomes exact. We focus not only on the bound states [70] but also on the photon and emitter dynamics [71, 72], keeping in mind a special concern on genuine NH phenomena such as point-gap band topology. While it is beyond the scope of the present work, our framework also applies to the many-body regime [10, 70, 73, 74], which could be a fruitful topic for future studies.

We provide a few case studies on several minimal NH models, finding that they already exhibit unexpectedly rich phenomena. As already highlighted in Ref. [75], the NH skin effect results in the so-called “hidden” bound states that behave very differently from the usual bound states in Hermitian systems. For example, there are the remarkable property that their energy is exactly pinned to the emitter detuning. This property turns out to remain valid for multiple emitters. In addition, the dynamics of a photon emitted into such a NH bath may differ a lot from free propagation, as can be understood from the generalized Brillouin zone (GBZ), a concept originally developed to explain the skin effect quantitatively [76, 77]. Also, we show how to utilize the NH degrees of freedom to realize non-exponential (typically algebraic) emitter decay, which is usually invisible in (one-dimensional) Hermitian systems due to the existence of stable bound states. In particular, we provide further detail on the passive $PT$-symmetric lattice studied in Ref. [75] and quantitatively explain the exponents of algebraic decay. We also provide a few more examples exhibiting non-exponential decay in both 1D

† flore.kunst@mpl.mpg.de
and 2D.

The rest of the paper is structured as follows. In Sec. II, we introduce the general framework for describing two-level emitters coupled to a NH bath with both coherent hopping and collective one-body loss. We also present a formal solution within the single-excitation sector. In Sec. III, we present the first case study on the general Hatano-Nelson model, extending the unidirectional limit considered in Ref. [75]. This example showcases the impact of NH topology. In Sec. IV, we present the second case study on a Wick-rotated (i.e., multiplied by $i$) Hermitian 1D model rendering it fully anti-Hermitian. We also discuss some general features of such a construction based on Wick-rotation. In Sec. V, we present the third case study on two models with EPs in 1D and 2D. In particular, we provide quantitative explanations to the algebraic atom decays observed in Ref. [75]. In Sec. VI, we discuss some common features of these models as well as the possible experimental implementations. Finally, we summarize the paper and provide an outlook in Sec. VII.

II. GENERAL FRAMEWORK

In this section, we present a general framework for studying quantum emitters in nanophotonic lattices that are completely captured by a NH description. We also provide a formal analytical solution to the eigenstate problem as well as the nonequilibrium dynamics.

A. Equation of motion

We consider $N$ (not necessarily identical) quantum emitters, modeled as two-level atoms, coupled to a $d$-dimensional nanophotonic lattice $\Lambda \subset \mathbb{Z}^d$ with engineered dissipation. Under the Markovian and rotating-wave approximations, in the rotating frame, the entire equation of motion is given by the Lindblad master equation

$$\dot{\rho}_t = -i[\hat{H}_a + \hat{H}_p + \hat{V}, \rho_t] + \mathcal{L}_a \rho_t + \mathcal{L}_p \rho_t.$$  \hspace{1cm} (1)

Here the coherent part consists of three terms. The atom Hamiltonian reads

$$\hat{H}_a = \sum_{n=1}^{N} \Delta_n \hat{\sigma}_n^{ee},$$  \hspace{1cm} (2)

where $\hat{\sigma}_n^{ww'} \equiv |w_n\rangle \langle w_n'| (w, w' = e, g)$ and $\Delta_n$ is the coherent detuning of the $n$th atom. The photon Hamiltonian takes a general (number-conserving) quadratic form

$$\hat{H}_p = \sum_{r, r' \in \Lambda} \sum_{s, s' \in I} J_{r, s; r', s'} \hat{a}_{r, s} \hat{a}_{r', s'},$$  \hspace{1cm} (3)

where $I$ is a set of internal states per unit cell that may involve, e.g., polarization or/and sublattice degrees of freedom, and

$$\hat{V} = \sum_{n=1}^{N} \sum_{i=1}^{m} \left( g_{ns} \hat{\sigma}_n^{eg} \hat{a}_{r, s} + \text{H.c.} \right),$$  \hspace{1cm} (4)

where $\gamma_n$ is the decay rate of the $n$th atom and $D[\hat{\sigma}^{eg}] \equiv \hat{L} \cdot \hat{L}^\dagger - \{\hat{L}, \hat{L}^\dagger\}/2$ is the Lindblad superoperator, and collective photon loss:

$$\mathcal{L}_p = \kappa \sum_{r \in \Lambda} \sum_{\mu = 1}^{m} D[\hat{L}^\mu],$$  \hspace{1cm} (6)

where $\kappa$ controls the loss rate, $\mu$ labels the dissipation channel, and $\hat{L}^\mu$ takes the following form:

$$\hat{L}^\mu = \sum_{r' \in \Lambda} \sum_{s' \in I} \hat{a}_{r', s'}. $$  \hspace{1cm} (7)

See Fig. 1 for a schematic illustration of this setup.

The effective NH Hamiltonian of Eq. (1) can be computed via

$$\hat{H}_{\text{eff}} = \hat{H}_a + \hat{H}_p + \hat{V} - \frac{i}{2} \sum_{n=1}^{N} \gamma_n \hat{\sigma}_n^{eg} \hat{\sigma}_n^{eg} - \frac{i}{2} \kappa \sum_{r \in \Lambda} \sum_{\mu = 1}^{m} \left( \hat{L}^\mu \right)^\dagger \hat{L}^\mu,$$  \hspace{1cm} (8)

FIG. 1. In our general setup, two-level atoms are coupled to a NH lattice with both coherent hopping $J$ (blue arrow) and collective loss $\kappa$ (red box), which are described by Eqs. (3) and (6), respectively. The atoms themselves undergo spontaneous decay, as is captured by Eq. (5). While not shown in the figure, the atom-photon detuning is generally nonzero [cf. Eq. (2)].
and reads
\[ \hat{H}_{\text{eff}} = \sum_{n=1}^{N} \Delta_n \hat{\sigma}^{ec}_n + \sum_{r,r' \in \Lambda} \sum_{s \in I} \hat{J}_{rs,r's'} \hat{\sigma}^{\dagger}_{rs} \hat{\sigma}_{r's'} + \sum_{n=1 \leq s \leq I} (g_{ns} \hat{\sigma}^{ge}_n \hat{\sigma}^{\dagger}_{rs} + \text{H.c.}), \] (9)
where both the detuning
\[ \Delta_n = \Delta^{c} - \frac{i}{2} \gamma_n \]
and the photon hopping amplitudes
\[ \hat{J}_{rs,r's'} = J_{rs,r's'} - \frac{i}{2} \kappa \sum_{\mu=1}^{m} \sum_{r'' \in \Lambda} \rho^{*} \rho_{rs,r''} \rho_{r''r's'} \] (10)
become complex. One can check, that since \( \dot{\hat{\rho}} \)'s only entail annihilation operators, starting from a single excitation state like \( \rho_0 = |\psi(0)\rangle\langle\psi(0)| \) with \( |\psi(0)\rangle = \hat{\sigma}^{ge}(g) \otimes |\text{vac}\rangle \), where \( g \equiv (g_1, g_2, \ldots, g_N) \) and \( |\text{vac}\rangle \) is the photon vacuum, the solution to the master equation (1) is given by [72, 78]
\[ \dot{\rho}_t = e^{-i\hat{H}_{\text{eff}}t} \rho_0 e^{i\hat{H}_{\text{eff}}t} + p_t |g\rangle\langle g| \otimes |\text{vac}\rangle \langle\text{vac}|, \]
(12)
where \( p_t = 1 - \text{Tr} \left[ e^{-i\hat{H}_{\text{eff}}t} \rho_0 e^{i\hat{H}_{\text{eff}}t} \right] \).

It is thus sufficient to analyze the NH effective Hamiltonian (9) if we focus on the single-excitation sector. In particular, we would like to consider the bound state
\[ |\psi_b\rangle = \left( \sum_{n=1}^{N} c_n^{\dagger} \hat{\sigma}^{ge} \right) |g\rangle \otimes |\text{vac}\rangle \] (13)
that satisfies \( \hat{H}_{\text{eff}} |\psi_b\rangle = E |\psi_b\rangle \) with nonzero atom weights and localized photon profiles near the atoms. We would also like to know the non-unitary real-time dynamics
\[ |\psi_t\rangle = \left[ \sum_{n=1}^{N} c_n(t) \hat{\sigma}^{ge} \right] |g\rangle \otimes |\text{vac}\rangle \]
(14)
governed by \( |\psi(t)\rangle = e^{-i\hat{H}_{\text{eff}}t} |\psi(0)\rangle \) starting from a localized or collective atomic excitation.

### B. Formal analytical solution

Assuming that the dissipative nanophotonic lattice is translation invariant and has periodic boundary conditions (PBC), i.e., \( J_{rs,r's'} = J_{r-r', s} \) and \( \rho^{*} \rho_{rs,r''} \rho_{r''r's'} \), we can rewrite Eq. (9) into
\[ \hat{H}_{\text{eff}} = \sum_{n=1}^{N} \Delta_n \hat{\sigma}^{ec}_n + \sum_{k \in \text{B.Z.}} \hat{\sigma}^{\dagger}_k \hat{h}_k \hat{\sigma}_k \]
(15)
\[ + \frac{1}{\sqrt{|\Lambda|}} \sum_{n=1}^{N} \sum_{k \in \text{B.Z.}} (\hat{\sigma}^{ge}_n \hat{c}_k g_{kn} + \text{H.c.}), \]
where \( \hat{a}_k = [\hat{a}_k]^{\dagger}_k \) with \( \hat{a}_k = |A|^{-1/2} \sum_{r \in \Lambda} e^{-ik \cdot r} \hat{a}_{rs} \) (|A| volume of \( \Lambda \)), \( g_{kn} = [g_{ns} e^{-ik \cdot r}]^{\dagger}_n \rangle s \in I \rangle \) and the NH Bloch Hamiltonian reads
\[ [h_{ks}] = J_{ks} s' - \frac{i}{2} \kappa \sum_{\mu=1}^{m} l_{\mu}^{*} s' l_{\mu}^{s} \]
(16)
where \( J_{ks} s' = \sum_{r \in \Lambda} J_{r,s} e^{-ik \cdot r} \) and \( l_{\mu}^{s} s' = \sum_{r \in \Lambda} l_{\mu}^{r} e^{-ik \cdot r} \) are the Fourier transformations of the photon hopping amplitudes (3) and the coefficients in the photon loss dissipators (7), respectively.

In terms of \( \hat{a}_k \)'s, the bound state can be rewritten as
\[ |\psi_b\rangle = \left( \sum_{n=1}^{N} c_n^{\dagger} \hat{\sigma}^{ge} + \frac{1}{\sqrt{|\Lambda|}} \sum_{k \in \text{B.Z.}} c_k \hat{a}_k \right) |g\rangle \otimes |\text{vac}\rangle, \]
(17)
where \( c_k = [\hat{c}_k]^{\dagger} \) contains the coefficients of all the photon modes with quasi-momentum \( k \). Further introducing the detuning matrix \( \Delta = \text{diag}(\Delta_1, \Delta_2, \ldots, \Delta_N) \), the atom-coefficient vector \( c_e = [c_{1e}, c_{2e}, \ldots, c_{Ne}]^T \) and the \( |J| \times N \) coupling matrix \( g_k = [g_{k1}, g_{k2}, \ldots, g_{kN}] \), we can explicitly write \( \hat{H}_{\text{eff}} |\psi_b\rangle = E |\psi_b\rangle \) as
\[ \Delta c_e + \frac{1}{|\Lambda|} \sum_{k \in \text{B.Z.}} g_k c_k = E c_e, \]
(18)
Eliminating \( c_k \)'s yields
\[ [E - \Delta - \Sigma(E)] c_e = 0, \]
(19)
where the self-energy \( \Sigma(z) \) is an \( N \times N \) matrix given by
\[ \Sigma(z) = \frac{1}{|\Lambda|} \sum_{k \in \text{B.Z.}} g_k^{*}(z - h_k)^{-1} g_k. \]
(20)
If we take the thermodynamic limit \( \Lambda \rightarrow \mathbb{Z}^d \), Eq. (20) becomes
\[ \Sigma(z) = \int_{\text{B.Z.}} \frac{d^{d} k}{(2\pi)^d} g_k^{*}(z - h_k)^{-1} g_k. \]
(21)
Since a bound state necessarily requires \( c_e \neq 0 \), we have
\[ \det(E - \Delta - \Sigma(E)) = 0. \]
(22)
Given a solution \( E \) to Eq. (22), we can in turn determine \( c_e \) (up to normalization) and then \( c_k \)'s via
\[ c_k = (E - h_k)^{-1} g_k c_e. \]
(23)
The normalization of the bound state implies
\[ c_{e} \left\{ 1 + \frac{1}{|\Lambda|} \sum_{k \in \text{B.Z.}} g_k^{*}(E - h_k)[(E^* - h_k)^{-1} g_k \c] c_e = 1. \right\} \]
(24)
The real-space photon profile can thus be determined by the inverse Fourier transformation, i.e.,

\[ c_{rs} = \frac{1}{|A|} \sum_{k \in B.Z.} c_{ks} e^{ik \cdot r} \int_{B.Z.} \frac{d^d k}{(2\pi)^d} e^{ik \cdot r}. \]  

(25)

Provided that \( E \) is not located on the complex photon dispersions, we can prove that (see Appendix A) the photon profiles are exponentially localized near \( r_n \)'s and thus \( |\psi_n\rangle \) is indeed a bound state.

To calculate the real-time dynamics, we employ the resolvent method (see Appendix B) to express \( c_{r}(t) = [c_1^r(t), c_2^r(t), \ldots, c_N^r(t)]^T \) as

\[ c_{r}(t) = \frac{i}{2\pi} \int_{-\infty}^{\infty} dE G_r(E + i0^+) e^{-iEt} c_{r}(0), \]  

(26)

where the atom (emitter) Green’s function \( G_r(z) \) is given by

\[ G_r(z) = \frac{1}{z - \Delta - \Sigma(z)}, \]  

(27)

which is again an \( N \times N \) matrix just like \( \Sigma(z) \) in Eqs. (20) and (21). Similarly, \( c_k(t) \)'s can be evaluated from

\[ c_k(t) = \frac{i}{2\pi} \int_{-\infty}^{\infty} dE G_k(E + i0^+) e^{-iEt} c_{r}(0), \]  

(28)

where the photon Green’s function \( G_k(z) \) is related to \( G_r(z) \) in Eq. (27) via

\[ G_k(z) = \frac{1}{z - h_k} g_k G_r(z). \]  

(29)

Again, the real-space photon dynamics can be obtained by Fourier transforming \( c_k(t) \) following Eq. (25). Introducing

\[ \Phi_r(t) \equiv \frac{i}{2\pi} \int_{-\infty}^{\infty} dE \int_{B.Z.} \frac{d^d k}{(2\pi)^d} e^{ik \cdot r - iEt}, \]  

(30)

which describes the bare photon propagation (in the absence of emitters) in real spacetime starting from a localized state at \( r = 0 \), we can explicitly express \( c_r(t) \equiv \Phi_c = \Phi_r(t) \) as a convolution:

\[ c_r(t) = -i \int_0^t dt' \Phi_r(t - t') c_r(t'), \]  

(31)

where the kernel function \( \Phi_r(t) \) is an \( |I| \times N \) matrix given by

\[ \Phi_r(t)_{sn} = \sum_{s' \in I} \Phi_{r-n_s}(t)_{s's} g_{ns}. \]  

(32)

One can check the self-consistency of Eq. (31) in the short-time regime: for a sufficiently small \( t \), we have \( |\Phi_r(t)_{sn}| \approx \delta_{r,r_n} g_{ns} \) and thus \( c_{rs}(t) \approx -ig_{ns} \sum_{n=1}^{N} \delta_{r,r_n} e^{in_n t} c_{n}(0) \), exactly reproducing the leading-order approximation \( \langle rs|(-iH_{\text{eff}})|\psi_0\rangle \), where \( |rs\rangle \equiv \hat{a}_r \hat{a}_s \) |vac\rangle.

III. CASE STUDY I — NON-HERMITIAN TOPOLOGY

In our first case study, we wish to examine the effect of NH topology on the dynamics of our system by studying a model that has a nonzero spectral winding number [31]. The most paradigmatic model with this feature is the Hatano-Nelson model [17], which consists of a periodic 1D chain with one degree of freedom with anisotropic nearest-neighbor (NN) hoppings. To realize this model in the effective NH Hamiltonian in Eq. (9), we choose the non-local dissipator \( \hat{L}_x = \hat{a}_x - i\hat{a}_{x+1} [31, 79] (x: \text{unit-cell label in 1D}) \), such that \( h_{x,x'} = \delta_{x,x'} - i\delta_{x+1,x'} \), and restrict hoppings along the 1D photonic lattice to NN only. Note that we have dropped the label \( s \) because we only have one degree of freedom per site. We then find that the effective photon hopping amplitudes [cf. Eq. (11)] read

\[ \tilde{J}_{x,x+1} = J - \kappa, \quad \tilde{J}_{x,x-1} = J + \kappa, \quad \tilde{J}_{x,x} = -i\kappa, \]  

(33)

where we set \( J_{x,x+1} = J_{x-1,x} = J \in \mathbb{R} \) and \( J_{x,x} = 0 \), which leads to the following effective photon Hamiltonian

\[ \hat{H}_{\text{eff},p} \equiv \sum_{x,x' \in \Lambda} \tilde{J}_{x,x'} \hat{a}_{x} \hat{a}_{x'}, \]

\[ = \sum_{x \in \Lambda} \left( (J - \frac{\kappa}{2}) \hat{a}_{x} \hat{a}_{x+1} + (J + \frac{\kappa}{2}) \hat{a}_{x+1} \hat{a}_{x} - i\kappa \hat{a}_{x} \hat{a}_{x} \right). \]

(34)

Fourier transforming this model, we find \( h_k \) in Eq. (15) to be

\[ h_k = \left( J - \frac{\kappa}{2} \right) e^{ik} + \left( J + \frac{\kappa}{2} \right) e^{-ik} - i\kappa \]

(35)

\[ = 2J \cos k - i\kappa (\sin k + 1), \]

which simply gives the band dispersion. The photon energy thus indeed forms a loop in complex energy plane. As it turns out, one can classify NH topological systems with point gaps using the winding number of the dispersion relation around any point \( z \) in its interior [31]:

\[ \text{ind}(h_k - z) \equiv \int_{-\pi}^{\pi} \frac{d\kappa}{2\pi} \partial_k \ln \det(h_k - z). \]  

(36)

The Hatano-Nelson model can be in two phases: \( \text{ind}(h_k - z) = -1 \) for \( J > 0 \) (stronger hoppings to the right) or \( \text{ind}(h_k - z) = 1 \) for \( J < 0 \) (stronger hoppings to the left).

In the following, we consider several emitters, each one coupled locally to a single site of the bath. Thus, the coupling function for the \( n \)th emitter reads \( g_{kn} = g_{n} e^{-i\kappa x_n} \). From Eq. (20), we can now compute the matrix elements of the self-energy as \( \Sigma_\text{II}(z)_{mn} = g_{m} g_{n} \phi(z, x_{mn}) \), where \( x_{mn} = x_m - x_n \) is the (signed) distance between the \( m \)th
and \( n \)th emitter, and

\[
\phi(z, x) = \frac{1}{2\pi} \int_{-\pi}^{\pi} dk e^{ikx} z^{-h_k}
\]

\[
= \frac{1}{2\pi i} \int dy ay^2 + by + c
\]

\[
= \frac{1}{2\pi i} \int dy \left( \frac{y^2}{-y} - \frac{y}{y - y_+} \right)
\]

\[
= \frac{1}{\sqrt{a}} \left[ \frac{\theta(1 - |y_+|) - \theta(1 - |y_-|)}{y - y_+} \right]
\]

where we assume \( a \neq 0 \). To go from the first line to the second we performed a change of variable \( y = e^{i\text{sign}(x)k}, \) such that the integral becomes a contour integral along the unit circumference in the complex plane (counter-clockwise). The denominator of the integrand is a second-order polynomial in the new variable \( y \) with coefficients:

\[
a = \text{sign}(x) \frac{\kappa}{2} - J, \quad b = z + i\kappa, \quad c = -\text{sign}(x) \frac{\kappa}{2} - J. \quad (38)
\]

Then, we split the integral using partial fractions; \( \delta = b^2 - 4ac = z^2 + 2i\kappa z - 4J^2 \) denotes the discriminant of the second-order polynomial, and \( y_{\pm} = (-b \pm \sqrt{\delta})/(2a) \) denote its roots. Lastly, we use residue integration—only the poles inside the unit circle contribute to the integral, so we express the result with the Heaviside’s step function \( \Theta(y) \). The expression above is valid also for \( x = 0 \), which corresponds to the single-emitter case, choosing either \( \text{sign}(0) = \pm 1 \). This (single-emitter) result has actually been obtained in Ref. [68]. However, Eq. (37) is not valid when the denominator of the integrand is a first-order polynomial, which may happen if there is hopping only in one direction, e.g., when \( J = \kappa/2 \). In that case, we obtain the following result: For \( x \geq 0 \),

\[
\phi(z, x) = \begin{cases} 
\frac{1}{z + i\kappa} \left( \frac{\kappa}{z + i\kappa} \right)^x, & \text{if } |z + i\kappa| > \kappa, \\
0, & \text{if } |z + i\kappa| < \kappa,
\end{cases} \quad (39)
\]

whereas for \( x < 0 \)

\[
\phi(z, x) = \begin{cases} 
0, & \text{if } |z + i\kappa| > \kappa, \\
-\frac{1}{\kappa} \left( \frac{\kappa}{z + i\kappa} \right)^{1+x}, & \text{if } |z + i\kappa| < \kappa.
\end{cases} \quad (40)
\]

This specific case is studied in the companion letter [75].

As we show next, some features of the self-energy are intimately related with the topology of the bath, as determined by the spectral winding number. Let us remind the reader of the following theorem (known as the argument principle [80]): For any analytic function \( f : \mathbb{C} \to \mathbb{C} \), the number of zeros counted with multiplicity inside the region delimited by the curve \( \gamma : [a, b] \to \mathbb{C}, \gamma(a) = \gamma(b), \) is equal to the winding number \( \text{ind}(f(\gamma)) \) (cf. Eq. (36)) of the curve \( f(\gamma) \) around the origin. Thus, for the polynomial \( p(y) = ay^2 + by + c \), with coefficients specified by Eq. (38), the number of roots inside the unit circle, which are the ones that contribute to the integral in Eq. (37), is the same as the index of the curve \( p(e^{ik}) \) for \( k \in [-\pi, \pi] \). If \( x \geq 0 \), \( p(e^{ik}) = e^{ik}(z - h_k) \), which implies that \( \text{ind}(p(e^{ik})) = 1 + \text{ind}(z - h_k) \). For \( x \leq 0 \), \( p(e^{ik}) = e^{ik}(z - h_k) \), thus, \( \text{ind}(p(e^{ik})) = 1 + \text{ind}(z - h_k) \). Now we can clearly see that for points \( z \) inside the loop defined by the bath’s complex dispersion relation \( h_k \), a situation that we will denote by \( z \in \ell \), the self-energy strictly vanishes, \( \phi(z \in \ell, x) = 0 \), if \( x \geq 0 \) and \( J < 0 \), or if \( x \leq 0 \) and \( J < 0 \). This result can be generalized to arbitrary 1D single-band NH lattices (see Appendix C).

### A. Bound states

Now, we can compute the energy \( E \) of the single-particle bound states using Eq. (22). For any given \( E \), the photonic component (wavefunction in the bath) of the bound states, is according to Eq. (25), given by \( \phi(E, d) \):

\[
c_x = \sum_{n=1}^{N} c_n^e g_n \phi(E, x - x_n). \quad (41)
\]

So, in general, the photonic component of any bound state is a superposition of exponentially-localized wavefunctions around each emitter. Importantly, \( \phi(E, x) \) does not have the same decay length for the left-half \( (x < 0) \) and right-half \( (x > 0) \) spaces. In fact, as we have just shown in Eqs. (39) and (40), \( \phi(E, x) \) may even vanish completely on one of the sides.

The shape of the bound states is intimately related to the characteristics of the bath and, in particular, to its topology. We can classify solutions in two classes that we call conventional bound states if \( E \) lies outside the loop and hidden bound states if \( E \) lies inside the loop. The former are composed of wavefunctions that decay on both sides of the emitters, see Fig. 2(a). The latter are composed of fully directional wavefunctions, even if the bath has finite hopping amplitudes in both directions, and they decay towards the direction of the weaker hopping amplitudes, see Fig. 2(b). They are unique to NH systems.
with nonzero spectral winding numbers. Strikingly, their energies are not affected by the presence of other emitters, contrary to what happens for conventional bound states (except when the bath is fully directional). This is due to the fact that $\Sigma(E)$ is strictly lower (lower) triangular if we label the emitters by increasing position for $E \in \ell$ if $J > 0$ ($J < 0$), so

$$\det[E - \Delta - \Sigma(E)] = \prod_{n=1}^{N} (E - \Delta_n), \text{ if } E \in \ell. \tag{42}$$

The equation $\det[E - \Delta - \Sigma(E)] = 0$ [cf. Eq. (22)] has, therefore, the possibility of having different detunings $\Delta_n$ for each emitter, and $\Delta \equiv \text{diag}[\Delta_1, \Delta_2, ..., \Delta_N]$. We can recognize these hidden bound states as the NH analogues of the vacancy-like bound states discussed in the Hermitian context [81]. Indeed, if we put a vacancy in the site to which an emitter is coupled we split the bath in two semi-infinite chains, whose eigenmodes can be computed using, e.g., the transfer-matrix method [82]. Skin modes correspond to those eigenvalues of the transfer matrix with absolute value smaller than one, which restricts their energy to the interior of $h_k$. Thus, the condition for a perfect vacancy-like bound state, namely, that the emitter detuning coincides with the energy of the vacancy mode (in this case, skin mode), is trivially satisfied whenever $\Delta$ lies inside the loop.

Interestingly, conventional bound states may require a sufficiently strong coupling constant $g$ to exist, depending on the value of $\Delta$. This is due to the fact that $[\Sigma(z)]_{mn}$ has a finite discontinuity when $z$ traverses the bath’s dispersion relation. This behavior is very different from the one expected for 1D Hermitian systems, where the divergence of the real part of the self-energy at the band edges of the bath’s spectrum guarantees the existence of bound states in every gap, regardless the value of $\Delta$ or $g$ [70].

### B. Photon-emission dynamics

In the companion letter [75], we obtained the analytic expression for the time evolution of a photon emitted from the atomic exciton in the unidirectional limit. While it seems impossible to have an analytic solution in the general case, we can readily perform numerical calculations. We demonstrate that the three different dynamical regimes still exist and can be well understood with the help of the GBZ [30, 77].

As mentioned previously, a unique feature of 1D NH nanophotonic systems is that the bound states may disappear if the light-matter coupling is too weak. In addition, the hidden bound states with eigenenergies inside the loop of the bath dispersion do not contribute to the dynamics and are thus invisible. One may thus naively expect that, in the absence of conventional bound states, the photon emission dynamics should resemble free propagation. This is indeed the case by choosing, e.g., $(J, \Delta, g) = (2.5, -i, 2)\kappa$. The corresponding dynamics is shown in Figs. 3(a) and (b). Unlike the unidirectional case, there is a nonzero leftward-propagating component, although it quickly decays. The oscillations result from the interference effect that appears already in the free-propagation dynamics, which is actually exactly solvable to be [83]

$$|c_x^{FP}(t)|^2 = \frac{(J + \kappa/2)^2}{(J - \kappa/2)^2} x \ J_x(\sqrt{4J^2 - \kappa^2 t})^2 e^{-2\kappa t} \tag{43}$$

starting from $c_x(0) = \delta_{x0}$, i.e., a photon localized at the origin. Here $J_x(z)$ is the Bessel function of the first kind and is known to exhibit sine-like oscillations for large $z$. Note that the amplification rate corresponds to the radius of the GBZ and the coefficient before $t$ is nothing but the bandwidth under the OBC.

However, if we change the detuning to be $\Delta = 0$, we find a spatial amplifying dynamics with a decay rate (at a fixed site) considerably smaller than free propagation. See Figs. 3(c) and (d). To gain some quantitative insights, we write down the running-wave contribution, which should dominate in the long time limit provided there is no bound state (or the bound state has a very short lifetime):

$$c_x^{RW}(t) = g \int_{-\pi}^{\pi} \frac{dk}{2\pi} \frac{e^{ikx - ih_k t}}{h_k - \Delta - \Sigma(h_k + i\eta_k)}, \tag{44}$$

where $\eta_k$ is a vanishingly small quantity such that $h_k + i\eta_k$ lies outside the loop. After straightforward calculations and the replacement $\beta \equiv e^{-ik}$, the running wave contribution can be expressed as the following contour integral:

$$c_x^{RW}(t) = \oint_{|\beta|=1} \frac{\beta^{-2}e^{-\kappa t}\beta^{-\Delta}\beta^{-i[(J+\kappa/2)\beta+(J-\kappa/2)\beta^{-1}]t}[(J+\kappa/2)\beta-(J-\kappa/2)\beta^{-1}]}{2\pi i \beta (J+\kappa/2)^2\beta^2 - (J-\kappa/2)^2\beta^{-2} - \Delta \beta^{-1}} \frac{d\beta}{2\pi i \beta} - g^2. \tag{45}$$

At least at large spacetime scales, one can justify from the stationary-phase approximation [84] that the above contour integral at the GBZ $|\beta| = \sqrt{(J-\kappa/2)/(J+\kappa/2)}$ [15] should be like free propagation. This contribution differs from Eq. (45) only in some residues associated with the poles of the integrand sandwiched by the GBZ and the original Brillouin zone $|\beta| = 1$. In the present case, there are three such poles (cf. inset in Fig. 3(c)) and the residue of the one lying on the imaginary axis turns out to be dominant and overwhelm the free-propagation-like component. We mention that there are actually two relevant poles in the previous case (cf. inset in Fig. 3(a)), but their residues have the same decay rate as free propagation but smaller spatial amplification rate. Therefore, the free-propagation-like component dominates in the previ-
A. General analysis

As pointed out in Ref. [75], the essential ingredient needed to realize such algebraic emitter decay is a bath with a vanishing damping gap (in the following denoted as critical), i.e., a bath whose spectrum touches the real axis. A simple way to design critical baths to consider fully anti-Hermitian baths obtained simply by multiplying \( i \) to Hermitian baths:

\[
\hat{H}_{\text{eff},\nu} = i\hat{H}_B, \quad \hat{H}_B^\dagger = \hat{H}_B.
\] (46)

From a dynamical point of view, such an operation is equivalent to making the real time imaginary, and thus may also be called a Wick rotation [16]. If \( \hat{H}_B \) has a negative spectrum with a band edge exactly at zero energy, then the resulting NH bath will have a vanishing damping gap. According to Eq. (21), the self-energy \( \Sigma \) in the anti-Hermitian model is related to the self-energy for the Hermitian counterpart \( \Sigma_B \) through

\[
\Sigma(z) = -i\Sigma_B(-iz).
\] (47)

Therefore, for real energy \( E \), if

\[
\Sigma_B(E \pm i0^+) = \delta(E) \mp i\Gamma(E)/2,
\] (48)

with real Lamb-shift \( \delta(E) \) and decay rate \( \Gamma(E) \), which is always the case if the couplings \( g_k \) are real, we have

\[
\Sigma(iE \pm 0^+) = -i\delta(E) \mp \Gamma(E)/2.
\] (49)

Since the role of the Lamb-shift and decay rate are reversed, the decay of the quantum emitter may be dramatically changed by Wick-rotating the bath, as will be illustrated in a concrete model in the following.

B. Example

As a simple example, we consider a 1D NN Hermitian lattice described by

\[
\hat{H}_B = -J \sum_{x \in \Lambda} \left( \hat{a}_{x+1}^\dagger \hat{a}_x + \hat{a}_x^\dagger \hat{a}_{x+1} + 2\hat{a}_x^\dagger \hat{a}_x \right),
\] (50)

whose dispersion relation is given by \( h_k = -2J(\cos k + 1) \). The “Wick-rotated” version \( \hat{H}_{\text{eff},\nu} = i\hat{H}_B \) has \( i\hbar_k \) as its dispersion relation, so it is critical, with a branch point at \( \epsilon_{\text{BP}} = 0 \). This model can be obtained in a 1D photonic lattice with a single site per unit cell, choosing \( J_{x,x'} = 0 \) and \( L_x = \hat{a}_x + \hat{a}_{x+1} \). Since the decay rate diverges as \( \Gamma(iE) \propto |E|^{-1/2} \) for \( E \to 0^- \), the algebraic decay is of the usual kind, i.e., proportional to \( t^{-3} \).

In fact, we can explicitly figure out the coefficient of the asymptotic algebraic decay. For a general branch cut terminating at a branch point \( \epsilon_{\text{BP}} \), its contribution can be calculated on the basis of the general formula [68]

\[
c_{\text{BC}}(t) \simeq \frac{e^{-i\pi(\nu+1)/2} \Gamma(\nu+1) F e^{-iz_{\text{BP}}t}}{2\pi \nu^1},
\] (51)
where $F$ and $v$ are determined by

$$\frac{1}{z - \Delta - \Sigma_r(z)} - \frac{1}{z - \Delta - \Sigma_i(z)} \simeq F(z - z_{BP})^v \quad (52)$$

for $z$ close to $z_{BP}$, with self-energy $\Sigma_r(z)$ ($\Sigma_i(z)$) evaluated from the right (left) side of the branch cut. For the Wick-rotated 1D lattice, according to the well-known result for 1D Hermitian NN lattice [72] and Eq. (47), we can easily write down the self-energy as

$$\Sigma(z) = \frac{g^2}{\sqrt{z(z + 4iJ)}}, \quad (53)$$

where the square root should be taken such that $\Sigma(z) \simeq g^2/z$ for large $z$. Therefore, for $z$ near $z_{BP} = 0$, the left-hand side (lhs) of Eq. (52) reads

$$\frac{2g^2\sqrt{z(z + 4iJ)}}{z(z + 4iJ)(z - \Delta)^2 - g^2} \simeq -\frac{4\sqrt{J}i}{g^2}z^{-1/2}, \quad (54)$$

implying that $v = 1/2$ and $F = -4\sqrt{J}/g^2$. Substituting these results into Eq. (51), we obtain

$$|c_{\text{BC}}(t)|^2 \simeq \frac{J}{\pi g^4} \frac{1}{t^3}, \quad (55)$$

which turns out to have no dependence on the detuning $\Delta$. As shown in Fig. 4(b), the asymptotic emitter decay is indeed given by Eq. (55). While the exact result should involve the contributions from the poles (corresponding to bound states) and another branch cut terminating at $-4iJ$, as shown in Fig. 4(c), all of these components decay exponentially in time and are thus quickly overwhelmed by Eq. (55).

Clearly, the long-time behavior of a quantum emitter in the Wick-rotated 1D lattice is very different from that in the original Hermitian lattice, for which $\Delta$ matters a lot and the algebraic decay is invisible [72]. On the other hand, it is well known in the context of NH topological phases that a Wick rotation is irrelevant, in the sense that it does not alter the topological classification at all [85]. There is actually no inconsistency. In the former case, we only have to focus on those eigenmodes with largest imaginary parts, which dominate the long-time dynamics. These modes may change dramatically upon the Wick rotation. In the latter case, our focus is whether two NH Hamiltonians can be continuously deformed into each other while keeping the gap open. Note that both the continuous path and gap persist upon the Wick rotation.

V. CASE STUDY III — EXCEPTIONAL POINTS

In our third case study, we provide further detail on the 1D model with alternating loss mentioned in Ref. [75]. We also propose a 2D model with exceptional lines in the band structure, which turns out to exhibit both non-exponential emitter decay and diffusive photon dynamics.

A. One dimension

We consider a 1D NH bath with a two-site unit cell. The two sublattice degrees of freedom are denoted as $A$ and $B$, as illustrated in the top of Fig. 5. Considering $L_x = \sqrt{2}a_{x,A}$ and again restricting the hopping in the 1D photonic lattice to NN by choosing $J_{xx,x',y'} = J(1 - \delta_{xx})(\delta_{xx'} + \delta_{x+1,x'-1} - 2\delta_{x,A,x'})$, we find that the effective NH photon Hamiltonian reads

$$\hat{H}_{\text{eff},p} = \sum_{x \in A} [J(\hat{a}_{x,A}^{\dagger} + \hat{a}_{x+1,A} \hat{a}_{x,B}) + \text{H.c.}] + i\kappa \hat{a}_{x,A}^{\dagger} \hat{a}_{x,A}]. \quad (56)$$

The corresponding NH Bloch Hamiltonian is given by

$$h_k = \begin{bmatrix} -\kappa & J(1 + e^{-ik}) \\ J(1 + e^{ik}) & 0 \end{bmatrix} \quad (57)$$

$$= J(1 + \cos k)\hat{\sigma}^x + J\sin k\hat{\sigma}^y - \frac{i}{2}\kappa(\hat{\sigma}^z + \hat{\sigma}^0),$$

whose energy dispersion reads

$$\epsilon_{k,\pm} = -\frac{i}{2} \pm \sqrt{2J^2(1 + \cos k) - \kappa^2 \frac{4}{4}}. \quad (58)$$

This system exhibits a passive parity-time (PT) symmetry [49]

$$\sigma^x(h_k + \frac{i}{2}\kappa\sigma_0)^* \sigma^x = h_k + \frac{i}{2}\kappa\sigma_0 \quad (59)$$

and has two EPs at $k_{\text{CP}} = \pm \arccos(\kappa^2/(8J^2) - 1)$ for $J > \kappa/4$. Depending on whether the atom is located on an even (sublattice $A$) or odd (sublattice $B$) site, we have $g_A = g$, $g_B = 0$ or $g_A = 0$, $g_B = g$, respectively.

For simplicity, we assume the same (real) single-photon Rabi frequency $g$ for all the emitters. Applying Eq. (20) and
followed by some calculations similar to Eq. (37), we obtain the entries in the self-energy matrix to be
\[
\Sigma_{mn}^{AA}(z) = \frac{g^2 z}{\sqrt{\delta}} \left[ y_{|x_m|}^{x_m} \Theta_+ - y_{|x_m|}^{x_m} \Theta_- \right],
\]
\[
\Sigma_{mn}^{BB}(z) = \frac{g^2 (z + i \kappa)}{\sqrt{\delta}} \left[ y_{|x_m|}^{x_m} \Theta_+ - y_{|x_m|}^{x_m} \Theta_- \right],
\]
\[
\Sigma_{mn}^{AB}(z) = \frac{g^2 J}{\sqrt{\delta}} \left[ F_x^{x_m}(y_+) \Theta_+ - F_x^{x_m}(y_-) \Theta_- \right],
\]
\[
\Sigma_{mn}^{BA}(z) = \frac{\Sigma_{nm}^{AB}(z)}{\sqrt{\delta}},
\]
where \( \Theta_\pm \equiv \Theta(1 - |y_\pm|), F_x(y) = y|x| + y|y^{-1}| \), and \( \delta \) is the discriminant of the second order polynomial \( ay^2 + by + c \) with coefficients
\[
a = c = -J^2, \quad b = -2J^2 + z(z + i \kappa),
\]
whose roots are given by \( y_\pm = (-b \pm \sqrt{\delta})/(2a) \). The superscripts in \( \Sigma_{mn} \) (e.g., \( AA \) or \( AB \)) are determined by the sublattices in which the emitters are located. In this case, at any point \( z \) of the complex plane, only one of the roots contributes since \( y_+, y_- = 1 \) (there are no regions with winding number other than 0). The analytic continuation of these functions to the second Riemann sheet is obtained replacing \( \Theta_\pm \rightarrow \Theta_\mp \).

1. Single-emitter dynamics

We denote the single-emitter self-energy as \( \Sigma_A(z) \equiv \Sigma_{mn}^{AA}(z) \) or \( \Sigma_B(z) \equiv \Sigma_{mn}^{BB}(z) \), depending on the sublattice to which the emitter is coupled. Setting \( |x_m| = 0 \) in the first two lines of Eq. (60), we obtain
\[
\Sigma_A(z) = \frac{g^2 z}{\sqrt{\delta}} (\Theta_+ - \Theta_-),
\]
\[
\Sigma_B(z) = \frac{g^2 (z + i \kappa)}{\sqrt{\delta}} (\Theta_+ - \Theta_-).
\]

No matter in which sublattice the emitter is located, we expect that the long-time dynamics is dominated by the algebraic decay since there is a branch point at the origin and all the poles have negative imaginary parts. Such a situation is similar to that of the Wick-rotated 1D lattice discussed in Sec. IVB (cf. Fig. 4(c)).

Quantitatively, we can again determine the explicit asymptotic form using Eqs. (51) and (52) (see Appendix D for detail). If the emitter is in sublattice \( A \) (with on-site loss) and the coupling is resonant (\( \Delta = 0 \)), by substituting Eq. (62) into Eq. (52), we obtain \( \nu = -1/2 \) and \( |F| = 4J/\sqrt{\kappa} \), leading to an asymptotic \( t \to 1 \) decay:
\[
|c_{BC}(t)|^2 \approx \frac{4J^2 \kappa}{\pi y^2} \frac{1}{t}.
\]

Otherwise, whenever the detuning \( \Delta \) is nonzero, we have \( \nu = 1/2 \) and \( |F| = g^2/(\Delta J^2 \sqrt{\kappa}) \), leading to the conventional \( t^{-3} \) decay:
\[
|c_{BC}(t)|^2 \approx \frac{g^4}{16\pi |\Delta|^4 J^2 K} \frac{1}{t^3}.
\]

For sufficiently small \( \Delta \), one may expect a crossover from \( t^{-1} \) to \( t^{-3} \), as indeed confirmed numerically in Fig. 5(a).

If the emitter is in sublattice \( B \), we always have \( \nu = 1/2 \) and \( |F| = 4J/(g^2 \sqrt{\kappa}) \), leading to the conventional \( t^{-3} \) decay:
\[
|c_{BC}(t)|^2 \approx \frac{J^2}{\pi g^4 K} \frac{1}{t^3}.
\]

Remarkably, similar to the case of the Wick-rotated 1D bath (55), the coefficient in Eq. (66) does not depend on \( \Delta \), as also confirmed numerically in Fig. 5(b).

As already mentioned in Ref. [75], the existence of EPs is not so crucial — we can still observe the above algebraic decays for \( 0 < J < \kappa/4 \). See Fig. 6 for an example. Moreover, the detuning to the EP \( \Delta = -i\kappa/2 \) does not make a qualitative difference either (although not shown here). What is important here turns out to be the criticality (gaplessness) of the system and the divergent density of states at the eigenvalue with zero imaginary part. Even though for Hermitian
systems this algebraic decay is also present, its contribution to the dynamics is obscured by the bound states, which have real energy and therefore do not decay.

An intriguing feature of the alternating-dissipation model described by Eq. (56) is the fact that the self-energy for emitters coupled to the A sublattice does not diverge, but it vanishes at the branch point $z_{\text{BP}} = 0$, i.e., $\Sigma_A(0) = 0$. This not only gives rise to the anomalous $t^{-1}$ decay mentioned already, but also to a non-decay eigenstate that may not necessarily have a localized photon profile (since the energy is not well separated from the photon spectrum; cf. Appendix A). Indeed, under PBC, one can check this eigenstate is nothing but the photon Bloch wave created by $\hat{a}^\dagger_{k,B}$ with $k = \pi$.

On the other hand, under OBC and provided that the emitter is coupled to the same sublattice (dissipative sublattice), depending on the parity of the number of unit cells separating the two emitters, the (anti)symmetric superposition has a nonzero overlap with a proper (normalizable) stable bound state, $\Sigma_-(0) = 0$ if $|x_{12}|$ is even [odd], whose wavefunction has the form (assuming $x_1 < x_2$)

$$|\psi_h\rangle \propto \left\{ \frac{J}{g} \left[ \hat{a}^{eg} - \sum_{x \geq x_2} (-1)^{x-x_2} \hat{a}^\dagger_{x,B} \right] \langle g | \otimes |\text{vac}\rangle \right\}.$$

As a consequence, an initial (anti)symmetric state does not fully decay, as shown in Fig 8(a) (blue curve), and part of the emitted photon remains trapped indefinitely between the two emitters, see Fig 8(b). This proper bound state does not exist when both emitters are coupled to the B sublattice, or to different sublattices. Note that such kind of two-emitter bound state (69) appears also in the absence of dissipation ($\kappa = 0$), as mentioned in Ref. [72].

In addition, with two emitters we can observe other algebraic decays, which are not present in the single-emitter case. For example, for two emitters coupled to the A sublattice out
of resonance with the bound state ($\Delta \neq 0$), we find a decay $\propto t^{-5}$, see Fig. 8(a) (green curve). Such a power law can again be quantitatively understood from the analytic expression of the self-energy (60) and the general formula in Eqs. (51) and (52) (see Appendix D for detail).

**B. Two dimensions**

Finally, let us consider a 2D model with an exceptional ring. As shown in Fig. 9(a), this model is inspired by the four-step SWAP model [87], which is arguably the simplest example of 2D anomalous Floquet insulators with chiral edge modes but zero Chern number (actually no dynamics in the bulk). The crucial difference here is that each arrow in Fig. 9(a) is interpreted as a unidirectional hopping rather than shift. Note that the unidirectional Hatano-Nelson model can be obtained from a 1D shift (Thouless pump [88]) via such a mapping. Recalling that the underlying open system is lossy, we know that the NH Bloch Hamiltonian reads

$$H_{\text{NH}} = \kappa \left[ \begin{array}{cc} 1 - 2i e^{i k_x} & 0 \\ 0 & 1 + 2i e^{-i (k_y + k_x)} \end{array} \right].$$  

where $\kappa$ is the chemical potential. This effective NH Hamiltonian can be obtained by choosing $H_{\text{NH}}$ to involve only NN hopping with amplitude $J = \kappa/2$, $m = 4$ and

$$\hat{L}_r^1 = \hat{c}_{rA} - i \hat{c}_{r-e_x,B}, \quad \hat{L}_r^2 = \hat{c}_{rA} - i \hat{c}_{r-e_y,B},$$
$$\hat{L}_r^3 = \hat{c}_{rB} - i \hat{c}_{rA}, \quad \hat{L}_r^4 = \hat{c}_{rB} - i \hat{c}_{r+e_x+e_y, A}. $$

Here the sublattice labels $A$ and $B$ are indicated in Fig. 9(a) and $e_{x,y}$ denotes the unit vector along $x, y$ direction.

Interestingly, apart from the background loss, the Bloch Hamiltonian (70) is the square root of the NN hopping model:

$$h_k + 2i\kappa \sigma_0)^2 = 2\kappa^2 (\cos k_x + \cos k_y) \sigma_0,$$  

where $\sigma_0$ is the $2 \times 2$ identity. Accordingly, one can readily obtain the band dispersions to be

$$\epsilon_k = -2i\kappa \pm \kappa \sqrt{2(\cos k_x + \cos k_y)},$$

implying that the EPs constitute the contour $k_x \pm k_y = \pi$ mod $2\pi$ (see Fig. 9(b)). Using the same property (72), one can analytically evaluate the single-emitter self-energy to be

$$\Sigma(z) = \int_{B.Z.} \frac{d^2 k}{(2\pi)^2} \frac{g^2 (z + 2i\kappa)}{z + 2i\kappa} K \left[ \left( \frac{2\kappa}{z + 2i\kappa} \right)^4 \right],$$

where $K(m) \equiv \int_0^{\pi/2} d\theta / \sqrt{1 - m \sin^2 \theta}$ is the complete elliptical integral of the first kind. One can check that there is a logarithmic branch point at the origin, around which the self-energy is dominated by [89]

$$\Sigma(z) \approx \frac{g^2}{2\pi\kappa} \ln \left( \frac{z}{8i\kappa} \right).$$

Such a singularity is similar to that found in the NN 2D Hermitian model at the band center [71, 72] and gives rise to a non-exponential atom decay, as numerically confirmed in Fig. 10. However, recalling that we are considering the square root of the NN 2D Hermitian model, the observed non-exponential decay should be attributed to the lower branch cut in the Hermitian model, where its contribution is overwhelmed by the lower bound states. In contrast, here this branch point has the largest imaginary part and thus dominates the long-time dynamics.

Quantitatively, for the time interval in our numerical calculations, we find that the non-exponential decay seems to be

![FIG. 8. (a) Emitter dynamics for a pair of quantum emitters coupled to the $A$ sublattice. The initial state is the symmetric superposition. The rest of parameters are $J = \kappa$ and $g = 1.5\kappa$. (b) Bath dynamics for a system with $x_{12} = 5$ and $\Delta = 0$ [the rest of parameters are the same as in panel (a)].](image)

![FIG. 9. (a) 2D NH lattice described by Eq. (70) (apart from a global loss). Here each arrow represents a unidirectional hopping, and the orange rectangle indicates a unit cell containing two sublattice degrees of freedom $A$ and $B$. (b) Real (upper) and imaginary (lower) band dispersions. The yellow lines indicate the exceptional ring.](image)
well described by $\propto t^{-2.5}$, as is also the case in the Hermitian model [71, 72]. However, by naively identifying the logarithmic scaling on the rhs of Eq. (52) as a zero power ($\nu = 0$), we may expect from Eq. (51) that the decay follows an algebraic law $t^{-2}$, possibly with logarithmic corrections that may account for the apparent inconsistency. Note that such an “actual” scaling has also been mentioned in Ref. [72].

In addition, just like the 1D (passive) PT-symmetric model (57) considered above, the gradient of Eq. (70) at the wave number with the largest imaginary part vanishes. While, unlike the 1D case, this does not lead to a divergent density of states, it significantly alters the photon dynamics, which turns out to be diffusive rather than ballistic, as numerically demonstrated in Fig. 10. This result may be understood from the fact that the free photon propagation in this 2D lattice is diffusive. Qualitatively, this may be understood from the fact that at each site the photon can only move along one of the two directions, so the dynamics should be rather constrained. Quantitatively, by expanding the NH Bloch Hamiltonian near the zero damping point $(k_x, k_y) = (\pi, \pi)$, we can estimate the diffusive photon (density) profile to be roughly $(k_t)^{-2} e^{-2r^2/(k_t)}$ up to a constant coefficient, which also implies the entire photon decay is critical and follows an algebraic law $t^{-1}$.

In fact, the diffusive photon propagation appears also in the passive PT-symmetric 1D model (57). This property in turn provides an intuition into the algebraic emitter decay observed in all these models: Since the emitted photon propagates very slowly, there is a larger (compared to the ballistic case) probability that it is absorbed (and then emitted) by the emitter again, leading to an enhancement of non-Markovianity. This argument also gives the intuition why the branch-cut contribution becomes large when the detuning is close to the band edges in Hermitian systems [72], near which the photon modes have almost vanishing group velocities.

Before ending this subsection, we would like to mention that neither the non-exponential decay nor the diffusive photon dynamics necessarily requires EEs. Indeed, we expect that similar phenomena may be observed in a Wick-rotated 2D Hermitian model (cf. Sec. IV). In order to observe exotic phenomena directly related to EEs, we may have to require the imaginary part of EEs to be the largest, a seemingly very uncommon situation. This could be yet another specific open problem for future studies.

VI. DISCUSSIONS

In this section, we discuss some general observations we found in our case studies. We also discuss the experimental relevance of our models.

A. Spectral stability

A unique feature of NH matrices is the spectral instability against perturbations. However, for all the examples considered above, where we put one or a few emitters in periodic lattices in the thermodynamic limit, the system spectra do not seem to be altered so much except for the bound states (see Fig. 11 for an explicit illustration). It is thus natural to ask whether the spectral stability is a universal property.

One can rigorously prove that the number of bound states away from the bare photon spectrum (i.e., excluding BICs) should always be finite in the thermodynamic limit. This is due to the identity theorem: for two analytic complex (holomorphic) functions defined on a connected domain, if they coincide at an infinite (countable infinity is enough) set of points with an accumulation point, they coincide on the entire domain [80]. Noting that $|\Sigma(E)|$ decays like $|E|^{-1}$ for large $|E|$, we know that zeros of the lhs of Eq. (22), which is a holomorphic function of $E$ and is dominated by $E^N$ for large $|E|$, should locate on a bounded region. Therefore, there should be an accumulation point if there are infinitely many zeros. However, according to the theorem, this is impossible since otherwise the lhs of Eq. (22) would be identically zero.

The remaining problem is whether dramatic spectral change could occur on the bare photon spectrum, such as a significant redistribution of the density of states. While we have no idea how to prove (or disprove) this statement, we conjecture this cannot occur either, provided that we keep $g$ finite or take the thermodynamic limit first. The intuition is that, according to the finite-size version of Eq. (22) which applies to any eigenstates, there should be a solution near each eigenvalue of $\hat{h}_k$, around which the self-energy becomes very sensitive. To explain a bit more why this problem could be
difficult, let us focus on a single emitter coupled to a single-band lattice with band dispersion $h_k$. One can readily check that Eq. (22) is equivalent to $F'(E) = 0$ with

$$F(z) = \prod_{k \in B.Z.} (z - h_k) e^{-\frac{|\Delta|^2}{2\kappa}(z-\Delta)^2}. \quad (76)$$

If the system is Hermitian and the detuning is real, noting that $F(h_k) = 0$, we can apply the mean value theorem for real analytic functions and obtain an eigenvalue between each pair of adjacent $h_k$’s. This result suggests a small deviation from the bare photon spectrum. For NH systems, however, $F(z)$ is generally a complex analytic function, for which the mean value theorem breaks down [90]. It is thus not obvious whether the zeros of $F'(z)$ are guaranteed to be around those of $F(z)$.

On the other hand, if we first take the large-$g$ limit for a finite-size system, we expect the system spectrum would be that of the NH lattice with some vacancy defects at the sites directly coupled to the emitters [81]. This may significantly alter the spectrum (see the right-bottom panel in Fig. 11 for an example) due to the boundary condition sensitivity of NH systems, as will be discussed in the next subsection. Note that the non-commutativity between thermodynamic limit and certain limit of coupling strength has already been highlighted in Refs. [31, 91] for NH lattices alone.

### B. Impact of boundary conditions

As an important implication of the instability of NH matrices against perturbations, it is known that both spectra and eigenstates of NH systems may dramatically change under different boundary conditions. Indeed, such boundary condition sensitivity appears in any NH system with skin effect, exemplified by the Hatano-Nelson model. This is also the case in the presence of emitters. For example, for the Hatano-Nelson model (35), one can check that while all bound states are localized near the emitter under PBC, all the eigenstates are localized at one boundary under the OBC, provided that the coupling strength is not so strong. This applies particularly to those bound-state like modes (whose eigenvalues obviously locate outside the “bulk” spectrum under the OBC) in the upper panels in Fig. 11.

On the other hand, we found that the atom-decay and photon-emission dynamics do not depend on the boundary condition, at least in the short-time regime. In fact, it has recently been proved for an arbitrary NH lattice with finite-range hopping that the wave propagation in the bulk is (almost) not altered by the boundary condition [92]. The proof applies directly to our setups and justifies the boundary insensitivity of bulk dynamics in general. Here, we provide an alternative argument based on the equivalence of Lindblad dynamics and NH Hamiltonian evolution in the single-particle sector of a lossy Markovian open system. By further imposing locality, we know that the Lindblad dynamics satisfies the Lieb-Robinson bound [93], and thus so does the NH Hamiltonian evolution. This further implies that the dynamics in the bulk should have weak boundary-condition dependence [94].

It is worthwhile to mention that the Lieb-Robinson bound is expected to be generally violated in NH systems with multiple particles [95, 96]. An intuitive understanding is that non-local measurements and post-selections are usually required to achieve NH Hamiltonian evolutions. This observation may potentially imply nontrivial boundary dependence for dynamics in NH nanophotonic systems upon going beyond the single-particle paradigm.

### C. Validity of the single-pole approximation

Perhaps the simplest approach to understanding the emitter dynamics in Hermitian baths is the single-pole approximation (SPA), which consists of replacing the self-energy $\Sigma(E)$, appearing in the integral (26), by a constant $\Sigma(\Delta)$. Such an approximation is also known as the Fermi’s golden rule or the Wigner-Weisskopf approach [97]. In this approximation, the effect of the whole bath is reduced to a shift (possibly with both a real and an imaginary component) of the emitter detuning:

$$c_e(t) \simeq e^{-i(\Delta + \Sigma(\Delta))t}. \quad (77)$$

This is valid in the weak-coupling regime ($g \ll \kappa, J$) and when the self-energy $\Sigma(E)$ is smooth around $E = \Delta$.

Within this approximation it is easy to understand that for Hermitian systems there is a transition in the emitter dynamics: the excited state population either decays or not depending on whether the emitter is resonant or not with the bath modes. At the transition between the two kinds of behavior the self-energy is singular, so the SPA breaks down—it is where the non-Markovian effects are the strongest.

One may wonder whether a similar effect occurs in NH systems. Is there a dramatic change in the emitter dynamics when the emitter is resonant with the bath modes? The answer is not so straightforward as in the Hermitian case, since the spectrum for OBC or PBC can be very different (especially in NH systems with point-gap topology). As it turns out, being resonant
with PBC modes may not have a big impact on the emitter dynamics. For example, in Fig. 12 we plot the decay rate for a single emitter coupled to the unidirectional Hatano-Nelson model, i.e., Eq. (35) with $J = \kappa/2$. The emitter dynamics is given exactly by

$$c_e(t) = R_+ e^{-iz_+ t} + R_- e^{-iz_- t}, \quad (78)$$

where $z_{\pm} = \Delta - i\kappa \pm \sqrt{(\Delta + i\kappa)^2 + 4g^2}$ and $R_{\pm} = \pm(z_{\pm} + i\kappa)/(z_{\pm} - z_-)$. The “exact” decay rate, which is taken as the imaginary part of the pole that is closest to $\Delta$ (if $\text{Re} \Delta > 0$, or $z_-$ otherwise), agrees well with the one given by the SPA all over the PBC spectrum. By contrast, they disagree when $\Delta$ is tuned close to the OBC spectrum, where, in fact, the self-energy diverges. Actually, for $\Delta$ tuned to the singularity $|z_+ - \Delta| = |z_- - \Delta|$ and $|R_+| = |R_-|$, so in that case the SPA breaks down, no matter how small $g$ is.

Let us provide a plausible argument about why the breakdown of SPA is more relevant to the spectrum under OBC instead of PBC in 1D. In general, a 1D NH Bloch Hamiltonian $h_{k\mu}$ may exhibit some nontrivial spectral winding topology so that its spectrum forms one or several loops. The self-energy can be evaluated as (cf. Eq. (21))

$$\Sigma(z) = \int_{|\beta|=1} \frac{d\beta}{2\pi i\beta} g_{\beta}(z - h_{\beta})^{-1} g_{\beta}, \quad (79)$$

where we have replaced $k$ by $\beta = e^{-ik}$. Recalling that the NH lattice is assumed to be short-ranged and the atom-photon coupling is on-site, we know that $h_{\beta}$ and $g_{\beta}$ are analytic (on the whole complex plane excluding $\beta = 0, \infty$) and so is $\Sigma(z)$ outside the loop. As long as the spectrum of $h_{\beta}$ does not touch $z$, one can freely deform the integral contour to a circle with arbitrary radius, which actually corresponds to the twisted boundary condition with an imaginary flux [17, 98], while keeping the integral result invariant. This also gives a natural way of analytically extending $\Sigma(z)$, since the spectrum of $h_{\beta}$ might shrink on a deformed contour. Denoting $D$ and $D'$ as the interiors of the original and shrunk spectra, we know that $\Sigma(z)$ can be analytically extended to $D \setminus D'$ via the deformation. In fact, it has been shown that the common part (set intersection) of the interior of the spectra of $h_{\beta}$ for various contours gives nothing but the OBC spectrum [40]. This implies that the analytic continuation of $\Sigma(z)$ is possible outside the OBC spectrum. Also, the analytically continued $\Sigma(z)$ necessarily exhibits some singularities (divergence) on the OBC spectrum, where perturbative analysis in terms of small $g$ breaks down and so does the SPA.

D. Experimental implementations

Many experimental platforms exist in which non-Hermitian lattice Hamiltonians (see for example the overviews in Refs. [15, 16]), or even the full Lindbladian dynamics (see, e.g., Refs. [99–101]) can be realized. In the systems considered in this paper, one or multiple additional modes or qubits (emitters) have to be coupled to the lattice. To make contact with the typical set-up in quantum optics, the emitters need to effectively be two-level systems, such as atoms or qubits. While this is not required to study the single-particle effects that we discuss here, it will be crucial to observe many-particle effects such as Dicke superradiance. Closest to the idea of emitters coupled to NH baths are realizations such as atoms coupled to nanophotonic structures [1]. In such devices, loss of photons in the bath naturally occurs, but it may be difficult to control. Better control is afforded in synthetic platforms, such as superconducting qubits coupled to superconducting metamaterials [2, 5], or ultracold atoms in optical lattices (see proposal in Ref. [70]). Since all of the physics discussed here is single-photon physics, having two-level emitters is not strictly necessary, and any synthetic platform in which NH arrays can be (weakly) coupled to isolated modes constitutes a viable platform. In the following, we describe a concrete idea how collective loss may be engineered in synthetic platforms.

A key challenge in any platform is to introduce spatially non-local collective loss as described by Eq. (7). A general idea is to introduce some auxiliary rapidly decaying modes and couple them coherently and non-locally to the primary degrees of freedom. After adiabatically eliminating these fast modes [102], we will end up with a collective loss of the primary degrees of freedom. This technique has been described in detail in Ref. [79, 103, 104] and demonstrated experimentally in coupled resonators [105]. Josephson junctions [106] and optomechanics [107, 108]. See Fig. 13(a) for an illustration for the minimal two-mode setup. In general, if we can introduce a set of auxiliary degrees of freedom $b_{\mu}$ on the same lattice, where $\mu = 1, 2, ..., m$ and each internal state $\mu$ undergoes on-site loss with decay rate $\kappa_{\mu}$, we can engineer the desired collective loss operators $L_{\mu}$’s by coupling these auxiliary modes to the primary photon modes of interest through

$$\hat{H}_\mu = \sum_{\mu_{r},s} \sum_{r,s' \in I} (\sqrt{\Gamma_{\mu}} \hat{d}_{\mu}^{\dagger}_{rr's} \hat{b}_{rr's}^{\dagger} + \text{H.c.}), \quad (80)$$

provided that $\kappa_{\mu}$ is large enough compared to other parameters such that the adiabatic elimination is well justified. Here, we provide a concrete example of implementing the 2D model in Eq. (70). As shown in Fig. 13(b), there are four auxiliary modes (pink circles) associated with one unit cell, each coupled to two nearest primary modes (gray circles). To realize
the jump operators in Eq. (71), we should fine-tune the couplings between the auxiliary and primary modes indicated by the solid bonds in Fig. 13(b) to be $J_{ap}$, while those indicated by the colored bonds to be $-J_{ap}$.

Let us provide a bit more detail about how to realize the models we studied on specific experimental platforms. We will specifically focus on platforms that directly extend to the many-body regime, which requires non-linear emitters. Ultracold atoms in optical lattices have been proposed as a candidate for realizing Hermitian nanophotonic systems [7] and NH lattices [31, 109, 110]. Following these proposals, a localized emitter decaying into a bath can be simulated by employing two (meta)stable states of a bosonic atom $|s\rangle$ and $|g\rangle$, trapped in a state-dependent optical lattice that is very deep for $|s\rangle$ and shallow for $|g\rangle$. In this configuration, the atom is localized if it is in $|s\rangle$ (corresponding to an excited emitter) but itinerant if it is in state $|g\rangle$ (corresponding to a photon). Using a two-photon transition via an excited state driven by two lasers, the stationary atom in $|s\rangle$ can be coupled coherently to itinerant atoms at a specified frequency [7]. Single-site addressing can be employed to flexibly engineer the positions of the emitters. The hopping amplitudes with complex phases may be engineered by using techniques developed for generating artificial gauge fields [111, 112]. When going to the many-body regime, we can use Feshbach resonances [113] to set the interactions among the photons $|g\rangle$ and between photons $|g\rangle$ and emitters $|s\rangle$ to zero, while enforcing an effective two-level nonlinearity by making the interaction among $|s\rangle$ large. Finally, spatially dependent loss can be introduced via another Raman transition to an untrapped state.

Superconducting circuits serve as yet another ideal platform. Here, the two main ingredients could be transmon qubits [114] and a superconducting metamaterial, as demonstrated in Ref. [115]. To control the interactions between modes, tunable couplers can be used, which have been demonstrated in many different settings (see Ref. [116] and references therein). Non-reciprocal coupling requires an effective gauge field in addition to dissipation, which can be achieved through parametric driving [117]. Passive implementations have also been realized [118]. This control can then be used to directly realize the scheme in Fig. 13; this has been demonstrated for few modes already [105, 106].

Before ending this subsection, we would like to discuss the possibility of exciting bound states in NH nanophotonic systems, a topic with particular experimental interest. In the context of waveguide quantum electrodynamics, particular attention has been devoted to BICs, which may arise when retardation in the waveguide is no longer negligible [119]. From the point of view of applications, an important question is how this state can be addressed and detected. Since a BIC is an eigenstate of the Hermitian emitter–waveguide Hamiltonian in the single-excitation subspace (e.g., Eq. (67) in the zero dissipation limit), it cannot be excited by a single-photon wavepacket, but instead requires carefully engineered two-photon wavepackets [120]. To reach optimal excitation probability, very long pulses have to be used [121]. The reason why single-photon wavepackets do not suffice can easily be understood by calculating the time-dependent overlap of a wavepacket $|\psi(t)\rangle$ with the bound-state wavefunction $|\psi_b\rangle$:

$$\langle \psi_b | e^{-i\hat{H}_{\text{Hermitian}} t} | \psi(0) \rangle = e^{-iE_b t} \langle \psi_b | \psi(0) \rangle, \quad (81)$$

where $\hat{H}_{\text{Hermitian}} | \psi_b \rangle = E_b | \psi_b \rangle$. In contrast, a key feature of NH systems is that left- and right-eigenstates of the Hamiltonian are distinct and that eigenstates are no longer necessarily orthogonal and thus Eq. (81) ceases to hold. As a result, the overlap between the bound state $|\psi_b\rangle$ and the time-evolved state $|\psi(t)\rangle$ is no longer conserved and therefore, in
stark contrast to Hermitian systems, the bound state can be excited from the continuum. We illustrate this fact with a simple example involving one emitter coupled to a Hatano-Nelson chain, see Fig. 14.

We note that the (complex) overlap \( \langle \psi_n | \psi(t) \rangle \) is a linear combination of the complex amplitudes of the state on each site. On photonic platforms this can be measured using homodyne tomography [122]. In a classical platform such as a mechanical metamaterial [46] this can directly be obtained from the trajectory of each resonator.

VII. CONCLUSION AND OUTLOOK

In summary, we have established a general framework for exploring NH physics in nanophotonic systems with engineered dissipation. We have also provided some case studies on a couple of minimal models that nevertheless exhibit rich phenomena. In particular, we have demonstrated that the hidden bound states (of multiple emitters) and unconventional photon-emission dynamics unveiled in Ref. [75] appeared also in the general Hatano-Nelson model. We have pointed out that an algebraic atom decay can be readily achieved by an analogically (Wick) rotated 1D lattice, and new exponents appear for multiple emitters in the passive PT-symmetric lattice with alternating loss. We have also studied a NH 2D model with non-exponential emitter decay and diffusive photon dynamics. Finally, we have discussed some general features and possible experimental realizations of these NH nanophotonic systems.

There are a lot of possible directions for future studies. Aside from the specific problems mentioned in the main text, the many-body generalization [10, 70, 74], where atomic (spin) and photonic (bosonic) excitations are no longer equivalent, could be a natural but challenging project. In this context, a question of particular interest is whether the unique NH features based on the single-particle picture, such as the point-gap topology, still play an essential role. On top of the ultrastrong-coupling regime [123–125] mentioned in Ref. [75], we would like to point out another relevant situation where\( \hat{H} \) has been engineered dissipation. We have also provided some case studies. The other problem is to study quantum emitters located at the boundaries of Hermitian topological systems (e.g., Chern insulators). Inspired by the Hermitian-NH correspondence discovered in Ref. [137], we expect such a setting may share some similarities with that in which emitters are embedded in the bulk of certain NH topological systems. For example, the emitter dynamics at the edge of a 2D Quantum Hall (Chern) insulator should be comparable to that in the bulk of the Hatano-Nelson model, as studied in this paper.

Appendix A: Exponential localization of the photon profile

We have shown in the main text that for a bound state \( c_k \) can be related to \( c_n \) via Eq. (23) and then \( c_r \equiv [c_n]_{s \in I}^T \) can be obtained by Eq. (25). Combining these two equations allows us to express \( c_r \) explicitly as \( c_r = \sum_{n=1}^{N_r} c_{rn} \), where

\[
 c_{rn} = c_n^T \int_{\text{B.Z.}} \frac{dk}{2\pi d} e^{i(k-r-n)} (\bar{E} - h_k)^{-1} |g_{ns}\rangle_{s \in I}. \tag{A1}
\]

Provided that \( E \) is outside the spectrum of \( h_k \) \( \forall k \in \text{B.Z.} \), there should exist \( K \in \mathbb{R}_+^d \) such that \( (E - h_k)^{-1} \) is analytic on \( D = \{ k : \text{Re} k < \text{B.Z.}, |\text{Im} k| \leq K \} \), no matter whether \( h_k \) is Hermitian or not [138]. Deforming the integral contour, we can express \( c_{rn} \) as

\[
 c_{rn} = c_n^T \int_{\text{B.Z.}} \frac{dk}{2\pi d} e^{i(k+\bar{K})} (\bar{E} - h_k+i\bar{K})^{-1} |g_{ns}\rangle_{s \in I}, \tag{A2}
\]

as long as \( |\bar{K}| \leq K \). In particular, we can choose \( \bar{K} \) such that \( |\bar{K}| = K \) while the sign of each spatial component is the same as that of \( r - r_n \). In this case, we can bound the vector norm of \( c_{rn} \) from above by

\[
 ||c_{rn}|| \leq C_n e^{-K' \cdot (r-r_n)}, \tag{A3}
\]

where \( C_n = |c_n^T| M \sqrt{\sum_{s \in I} |g_{ns}|^2} \) with \( M \equiv \max_{k \in D} \|(E - h_k)^{-1}\| \) does not depend on \( r \). It is now clear from Eq. (A3)
that the photon profile should be exponentially localized near the atoms.

We note that the idea of analytically extending $k$ dates back to the demonstration of Wannier localization in 1D Hermitian lattices over sixty years ago [139]. Here we emphasize that this idea applies equally to NH systems. Moreover, unlike the Wannier state which may not be exponentially localizable in two and higher dimensions due to, e.g., a nontrivial Chern number [140], the bound state is always exponentially localized, just like the correlation in the ground state of a gapped phase with local interactions [141]. For free-fermion systems, one may not be able to find a set of (filled) Bloch states that are also continuous in $k$ due to a topological obstruction such as a nontrivial Chern number.

Appendix B: Resolvent method

We consider lossy dynamics generated by a NH Hamiltonian $\hat{H}$ with no eigenvalue above the real axis in the complex energy plane. Suppose that the initial state $|\psi_0\rangle$ is inside a subspace onto which the projector is $\hat{P}$, i.e., $\hat{P}|\psi_0\rangle = |\psi_0\rangle$, we can decompose $|\psi_t\rangle = e^{-i\hat{H}t}|\psi_0\rangle$ into $\hat{P}|\psi_t\rangle + \hat{Q}|\psi_t\rangle$ ($\hat{Q} \equiv 1 - \hat{P}$ is the complement of $\hat{P}$). The component $\hat{P}|\psi_t\rangle$ can be evaluated by

$$
\hat{P}|\psi_t\rangle = \hat{P} e^{-i\hat{H}t} \hat{P}|\psi_0\rangle = \frac{i}{2\pi} \int_{-\infty}^{\infty} d\omega \hat{G}_P(\omega + i0^+) e^{-i\omega t}|\psi_0\rangle,
$$

where $\hat{G}_P(z)$ is the constrained propagator defined as

$$
\hat{G}_P(z) \equiv \hat{P}(z - \hat{H})^{-1} \hat{P}.
$$

Likewise, the component $\hat{Q}|\psi_t\rangle$ can be evaluated by

$$
\hat{Q}|\psi_t\rangle = \frac{i}{2\pi} \int_{-\infty}^{\infty} d\omega \hat{G}_{QP}(\omega + i0^+) e^{-i\omega t}|\psi_0\rangle,
$$

where $\hat{G}_{QP}(z)$ is another constrained propagator defined as

$$
\hat{G}_{QP}(z) \equiv \hat{Q}(z - \hat{H})^{-1} \hat{P}.
$$

One can check that

$$
\hat{G}_P(z) = \hat{G}_P^{(0)}(z) + \hat{G}_P^{(0)}(z)\hat{H}_{PQ}\hat{G}_{QP}(z),
\hat{G}_{QP}(z) = \hat{G}_{QP}^{(0)}(z)\hat{H}_{QP}\hat{G}_P(z),
$$

where $\hat{H}_{PQ} \equiv \hat{P}\hat{H}\hat{Q}$, $\hat{H}_{QP} = \hat{Q}\hat{H}\hat{P}$ and

$$
\hat{G}_P^{(0)}(z) \equiv \hat{P}(z - \hat{H})^{-1} \hat{P},
\hat{G}_{QP}^{(0)}(z) \equiv \hat{Q}(z - \hat{H})^{-1} \hat{Q},
$$

with $\hat{H}_P \equiv \hat{P}\hat{H}\hat{P}$ and $\hat{H}_Q \equiv \hat{Q}\hat{H}\hat{Q}$. Combining the two equations in Eq. (B5) by eliminating $\hat{G}_{QP}(z)$, we obtain

$$
\hat{G}_P(z) = [\hat{G}_P^{(0)}(z)^{-1} - \hat{\Sigma}(z)]^{-1},
\hat{\Sigma}(z) = \hat{H}_{PQ}\hat{G}_Q^{(0)}(z)\hat{H}_{QP},
$$

which in turn implies [due to the second line in Eq. (B5)] that $\hat{G}_{QP}(z)$ can be expressed in terms of $\hat{G}_P^{(0)}(z)$, $\hat{G}_Q^{(0)}(z)$, $\hat{H}_{PQ}$, and $\hat{H}_{QP}$.

While the above formulas are formally the same as the well-known results for Hermitian systems [143], we emphasize that they apply equally to NH (lossy) systems and even NH projectors. As for the photon-emission problem discussed in the main text, however, the projector onto the atomic-excitation subspace is still Hermitian while both $\hat{H}_P$ and $\hat{H}_Q$ are NH in general. Concretely, we have

$$
\hat{H}_P = \sum_{n=1}^{N} \Delta_n \hat{\sigma}_n^z, \quad \hat{H}_Q = \sum_{k \in \mathbb{B}, \mathbb{Z}} \hat{a}_k^\dagger n \hat{a}_k,
$$

where all the notations follow those in Eq. (15). We focus on the single-excitation sector and choose the basis to be $\{\hat{\sigma}_n^z|g\rangle\}_{n=1}^{N}$ and $\{\hat{a}_{k,s}\hat{\sigma}_n^z|\text{vac}\rangle\}_{k \in \mathbb{B}, \mathbb{Z}, s \in \mathbb{I}}$, which constitute the subspaces of the projectors $\hat{P}$ and $\hat{Q}$, respectively. By substituting Eq. (B8) into Eqs. (B7) and (B5), we obtain

$$
\hat{G}_P(z) = G_e(z) \quad \text{and} \quad \hat{G}_{QP}(z) = |\lambda|^{-1/2} \sum_{k \in \mathbb{B}, \mathbb{Z}} G_k(z),
$$

where $G_e(z)$ and $G_k(z)$ are given in Eqs. (27) and (29) in the main text, respectively.

Appendix C: Vanishing self-energy at maximally winding regions

We consider a general 1D single-band NH lattice with finite range hopping. Denoting the largest leftward (rightward) hopping ranges as $q$ ($p$), the Bloch Hamiltonian (band dispersion) takes the following form:

$$
h_k = \sum_{n=-p}^{q} J_n e^{in\ell},
$$

where the hopping amplitudes $J_n$’s are complex in general. For the multi-emitter self-energy matrix, if the distance $x \geq 0$, the matrix element is proportional to the integral

$$
\phi(z, x) = \oint_{|\gamma|=1} \frac{dy}{2\pi i} \frac{y^{x+p-1}}{z y^p - \sum_{n=0}^{p+q} J_{n-p} y^n}.
$$

If ind$(h_k - z) = -p \neq 0$, which implies that no zeros of $z y^p - \sum_{n=0}^{p+q} J_{n-p} y^n$ are within the unit circle (according to the argument principle [80]), the above integral (C2) vanishes. Similarly, if $x \leq 0$, the matrix element is proportional to

$$
\phi(z, x) = \oint_{|\gamma|=1} \frac{dy}{2\pi i} \frac{y^{-x+q-1}}{z y^q - \sum_{n=0}^{q-p} J_{n+q} y^n}.
$$
If \( \text{ind}(h_k - z) = q \neq 0 \), which implies that no zeros of \( zy^q - \sum_{n=0}^{q} J_{-n+q} y^q \) are within the unit circle, the above integral vanishes.

Note that \( \{ z : \text{ind}(h_k - z) = -p \} \) or \( \{ z : \text{ind}(h_k - z) = q \} \) is the maximally winding regions, since the spectral winding number of \( h_k \) in Eq. (C1) can only take on integers among \([ -p, q ]\). For the Hatano-Nelson model (\( p = 1 \) and/or \( q = 1 \)), the maximally winding region is simply the interior of the spectral loop.

Let us provide another simple example showing that a nonzero winding number alone (i.e., not maximal in general) is not sufficient for pinning the eigenenergy of the (hidden) bound state at the complex detuning. Consider a 1D NH lattice with both NN and next-to-NN unidirectional hopping. The Bloch Hamiltonian reads

\[
h_k = \kappa (e^{-ik} - 1) + \kappa' (e^{-2ik} - 1). \tag{C4}
\]

The corresponding self-energy can be analytically obtained to be

\[
\Sigma(z) = \frac{g^2}{\sqrt{\delta}} (y_+ \Theta_+ - y_- \Theta_-), \tag{C5}
\]

where \( y_{\pm} \) are the roots of \( (z + i \kappa + i \kappa') y^2 - \kappa y - \kappa' = 0 \), with \( \delta = \kappa^2 + 4 \kappa' (z + i \kappa + i \kappa') \) is the discriminant and \( \Theta_{\pm} = \Theta(1 - |y_{\pm}|) \). By choosing, e.g., \( \kappa' = 2 \kappa \), we find that there is a non-maximally winding region (\( \text{ind} = -1 \)) on top of a maximally winding region (\( \text{ind} = -2 \)), as shown in Fig. 15. One can check that the self-energy (C5) identically vanishes in the maximally winding region, but otherwise has a nontrivial \( z \) dependence. As a result, if a complex detuningclinic has in a non-maximally winding region, we do not have a bound state with eigenenergy being exactly \( \Delta \) in general (cf. Fig. 15).

**Appendix D: Branch-cut singularities for the alternatingly lossy lattice (57)**

We provide quantitative explanations on the various exponents of algebraic atom decay observed in the passive \( PT \)-symmetric lattice (57) with alternating loss. Since we are only interested in \( |c_e(t)|^2 \), it suffices to know the absolute value of \( F \). Accordingly, we do not need to exactly identify \( \Sigma_{\text{ind}} \) but only have to know the amount of sudden jump in the self-energy. Noting that \( y_+ y_- = 1 \) for \( y_+ \) in Eq. (60), we know that the self-energy right before/after the jump is nothing but the coefficient before \( \Theta_+ / \Theta_- \) (or vice versa).

For a single-emitter in sublattice \( A \), the self-energy is given by Eq. (62). Therefore, the lhs of Eq. (52) (up to a sign, as is always the case in this Appendix) reads

\[
\frac{1}{z - \Delta - \frac{g^2 z^2}{\sqrt{\delta}}} - \frac{1}{z - \Delta + \frac{g^2 z^2}{\sqrt{\delta}}} = \frac{2g^2 z^2}{\delta (z - \Delta)^2 - g^4 z^4}. \tag{D1}
\]

where \( \delta = z(z + i \kappa)(z^2 + i \kappa z - 4J^2) \simeq -4i \kappa J^2 z \) for small \( z \) (i.e., \( z \) close to 0, which is the branch point). If \( \Delta = 0 \), the denominator of the rhs of Eq. (D1) is dominated by \(-g^4 z^2\) for small \( z \), leading to \( \nu = -1/2 \) and \( |F| = 4J^2 / (g^2 \sqrt{\kappa}) \). Otherwise, the denominator is dominated by \( \delta \Delta^2 \), leading to \( \nu = 1/2 \) and \( |F| = g^2 / (J \sqrt{\kappa} \Delta^2) \).

Similarly, for a single-emitter in sublattice \( B \), the self-energy is given by Eq. (63). The lhs of Eq. (52) thus reads

\[
\frac{1}{z - \Delta - \frac{g^2 (z + i \kappa)}{\sqrt{\delta}}} - \frac{1}{z - \Delta + \frac{g^2 (z + i \kappa)}{\sqrt{\delta}}} = \frac{2g^2(z + i \kappa)\sqrt{\delta}}{\delta(z - \Delta)^2 - g^4 (z + i \kappa)^2}, \tag{D2}
\]

where \( \delta \) follows that in Eq. (D1) (same applies hereafter). Unlike the previous case, now the denominator of the rhs of Eq. (D2) is always dominated by \( g^4 \kappa^2 \) for small \( z \) regardless of \( \Delta \), leading to \( \nu = 1/2 \) and \( |F| = 4J / (g^2 \sqrt{\kappa}) \). The results so far have already been mentioned in the main text.

We move on to the case of two emitters located in sublattice \( A \). The initial state is assumed to be in a symmetric superposition, so the self-energy reads

\[
\Sigma(z) = \Sigma_{1A}(z) + \Sigma_{\text{ind}}(z), \tag{D3}
\]

where \( \Sigma_{\text{ind}}(z) \) is given in Eq. (60). If the two emitters are in the NN unit cells, we have \( |x_{12}| = 1 \) in Eq. (60) and the lhs of Eq. (52) turns out to be

\[
\frac{1}{z - \Delta - \frac{g^2 z^2}{\sqrt{\delta}} (1 + y_+)} - \frac{1}{z - \Delta + \frac{g^2 z^2}{\sqrt{\delta}} (1 + y_-)} = J^2 \delta(z - \Delta)^2 - g^4 \delta z^2 (z - \Delta) - g^4 z^4 (z + i \kappa). \tag{D4}
\]

The numerator of the rhs of Eq. (D4) is always of \( O(z^{5/2}) \) for small \( z \). If \( \Delta = 0 \), the denominator is of \( O(z^2) \), leading to \( \nu = -1/2 \). However, the corresponding \( t^{-1} \) decay is invisible due to the (accidentally) stable bound states. Otherwise, the denominator is of \( O(z) \), leading to \( \nu = 3/2 \). The corresponding \( t^{-5} \) decay is visible (at least in the long-time limit) since now the bound state has a nonzero imaginary energy.

If the emitters are located in two next-to-NN unit cells, we have \( |x_{12}| = 2 \) in Eq. (60) and the lhs of Eq. (52) turns out to
be
\begin{equation}
\frac{1}{z - \Delta - \frac{g^2}{\sqrt{b}}(1 + y^2)} - \frac{1}{z - \Delta + \frac{g^2}{\sqrt{b}}(1 + y^2)} = \frac{g^2 b^2 \sqrt{\Delta} z}{J^4 (z - \Delta)^2 - g^2 b \delta z (z - \Delta) - g^4 b^2 \delta^2 z^2},
\end{equation}

where \( b = -2J^2 + z(z + i\kappa) \approx -2J^2 \) for small \( z \). The numerator of the rhs of Eq. (D5) is always of \( O(z^{3/2}) \). If \( \Delta = 0 \), the denominator is of \( O(z^2) \), leading to \( \nu = -1/2 \) and a corresponding \( t^{-1} \) decay. Otherwise, the denominator is of \( O(z^2) \), leading to \( \nu = 1/2 \) and a corresponding \( t^{-3} \) decay. All of these results have been numerically demonstrated in Fig. 8(a).
