BLACK HOLE-NEUTRON STAR Mergers and Short GRBs: A Relativistic Toy Model to Estimate the Mass of the Torus

FRANCESCO PANNARALE¹, AARYN TONITA¹, LUCIANO REZZOLLA¹,²

ABSTRACT

The merger of a binary system composed of a black hole and a neutron star may leave behind a torus of hot, dense matter orbiting around the black hole. While numerical-relativity simulations are necessary to simulate this process accurately, they are also computationally expensive and unable at present to cover the large space of possible parameters, which include the relative mass ratio, the stellar compactness and the black hole spin. To mitigate this and provide a first reasonable coverage of the space of parameters, we have developed a method for estimating the mass of the remnant torus from black-hole-neutron star mergers. The toy model makes use of the relativistic affine model to describe the tidal deformations of an extended tri-axial ellipsoid orbiting around a Kerr black hole and measures the mass of the remnant torus by considering which of the fluid particles composing the torus are on bound orbits at the time of the tidal disruption. We tune the toy model by using the results of fully general-relativistic simulations obtaining relative precisions of a few percent and use it to investigate the space of parameters extensively. In this way we find that the torus mass is largest for systems with highly spinning black holes, small stellar compactnesses and large mass ratios. As an example, tori as massive as $M_{\text{tor}} \simeq 1.33 M_\odot$ can be produced for a very extended star with compactness $C \simeq 0.1$ inspiralling around a black hole with dimensionless spin $a = 0.85$ and mass ratio $q \simeq 0.3$. However, for a more astrophysically reasonable mass ratio $q \simeq 0.14$ and a canonical value of the stellar compactness $C \simeq 0.145$, the toy model sets a considerably smaller upper limit of $M_{\text{tor}} \lesssim 0.34 M_\odot$.

Subject headings: gamma rays: bursts – black hole physics – stars: neutron

INTRODUCTION

The most widely accepted scenario to explain the phenomenology associated with short-hard gamma-ray bursts (SGRBs) involves the merger of either black hole (BH) neutron star (NS) systems or of binary NS systems (Nakar 2007). In either case, the remnant consists of a BH with negligible baryon contamination along its polar symmetry axis and of a hot massive accretion torus surrounding it, i.e., “neutrino wind”. At the same time, energy deposition by $\nu\bar{\nu}$ annihilation in the baryon-free funnel around the BH rotation axis powers relativistically expanding $e^\pm$ jets, which can give rise to the observed GRB emission.

The simulation of these events “ab initio” requires an adequate description of general relativity, relativistic (magnetohydrodynamics, and a proper microphysical equation of state. Typically, the only way to model these systems accurately is to resort to numerical-relativity simulations, solving consistently both the Einstein equations and those of relativistic hydrodynamics or magnetohydrodynamics. These simulations have made considerable progress in the last few years (see, for instance Oechslin & Janka 2007; Anderson et al. 2008; Baiotti et al. 2008; Yamamoto et al. 2008; Anderson et al. 2008; Liu et al. 2008; Giacomazzo et al. 2009; Rezzolla et al. 2010; Bauswein et al. 2010) for corresponding work on BH-NS binaries). Despite the fact that this type of simulations is now possible, they remain nevertheless both challenging and computationally intensive. Numerical simulations of NS-NS mergers have now reached a rather high level of accuracy [see Baiotti et al. (2009) and the discussion in the Appendix of Rezzolla et al. (2010)], and different codes have been shown to yield results that agree to 10% (at worse) when using the same initial data (Baiotti et al. 2010). However, the situation is much more uncertain in the case of BH-NS binaries, for which no direct comparison among different codes has been made yet and the results of the simulations from different codes are sometimes not in agreement. As an example, the merger of the same binary with mass ratio $1/3$ yields a torus with baryon mass which is $\sim 4\%$ of the NS in Etienne et al. (2009) and $\lesssim 0.001\%$ in Shibata et al. (2009). As a result, no reliable knowledge is available at the moment on how the mass of the torus depends on the most important parameters of the system: the mass ratio, the stellar compactness and the BH spin.

These problems, along with the need of a better understanding of the tidal disruption process, have pushed the parallel development of semi-analytical approaches to the problem. Shibata [1996], for instance, described the necessary conditions for the production of an accretion torus of appreciable size by requiring that the NS disruption occurs at a radial radius $r_{\text{tid}}$ that is larger than the innermost stable circular orbit (ISCO) of the BH $r_{\text{ISCO}}$. Unfortunately Shibata [1996] did not predict the mass of the resulting accretion torus except to assume that it vanishes when the radius of tidal disruption is less than that of the ISCO. A parallel systematic study has been pursued recently to exploit the relativistic “affine-
model" and describe the properties of the tidally deformed NS (Ferrari et al. 2009; Ferrari et al. 2010). Also in this case, however, the study has concentrated on the evolution of stationary configuration and has not made any prediction on the final outcome of the merger.

In this paper we attempt to bridge the gap between intensive numerical simulations and semi-analytical studies by establishing a way to estimate the mass of the resulting torus. We do this by taking the concept of the tidal disruption to its logical extreme. In other words, we model the NS in the binary as a relativistic tri-axial ellipsoid which is tidally distorted as it orbits in the tidal field of a rotating BH. When the tidal-disruption radius is reached, however, we assume the star to be composed of a system of non-interacting "fluid particles" which move on the corresponding geodesics. We therefore compute the mass of the torus as the integral of the masses of the particles which do not fall into the BH and do not escape to infinity. This clearly represents only a "toy model" for the complex dynamics of the merger process, but we show that, with a suitable tuning, it allows us to reproduce with good precision the large majority of the results obtained so far from more accurate but also considerably more expensive numerical relativity calculations. Most importantly, however, it provides a simple tool to better understand the complex dynamics of the tidal disruption and to cover at once the full space of parameters.

The structure of the paper is the following one. In Sect. 2 we describe the particular tidal model we use and then how we estimate the mass of the accretion torus. In Sect. 3 we show that by tuning the free parameter in our model we can reproduce results obtained within fully general-relativistic simulations, thus proving that the tool we build is solid. In Sect. 4 we present the results of our estimates, leaving an intuitive interpretation of the results and the conclusive overview to Sects. 5 and 6 respectively.

2. METHOD

To model the behaviour of the NS during the final stages of the inspiral of the mixed binary and before it merges with the BH, we use an improved version of the affine model which is presented in detail in Ferrari et al. (2009). An important difference with respect to that work is that we do not consider the prescriptions of the quasi-equilibrium approximation and, rather, follow the dynamics of the NS until it is disrupted by the BH tidal field. Furthermore, as mentioned in the Introduction, in addition to treating the NS as a tri-axial ellipsoid, we also decompose it into a large number of representative "fluid particles", whose kinematic properties will be used to study the motion of the NS matter after the tidal disruption. Our toy model is therefore composed of three logical parts: (i) the evolution of the NS deformation as it inspirals towards the BH; (ii) the modelling of the tidal disruption; (iii) the calculation of the mass building-up the torus. Each of these parts will be discussed separately in the remainder of this Section.

2.1. Neutron star deformation - The affine model

The idea of modelling stars as ellipsoids has a long history and a thorough analysis of incompressible ellipsoidal figures of equilibrium was performed by Chandrasekhar in 1969 (Chandrasekhar 1969). When modelling the NS deformation, we are addressing what is known as the compressible Roche-Riemann problem, in which one studies the behaviour of a compressible ellipsoid with uniform vorticity parallel to its rotation axis, orbiting a point mass or a rigid sphere. More specifically, we will be using an improved version of the affine model, which was developed in the '80s by Carter, Luminet and Marck to describe the encounters between a BH and a Newtonian star (Carter & Luminet 1982, 1983, 1985; Luminet & Marck 1985; Luminet & Carter 1986) and then applied to BH-NS binaries at the very end of the '90s (Wiggins & Laplace 2000). More recently, the Newtonian treatment of the star was upgraded to achieve a better description of the NS in mixed compact binaries (Ferrari et al. 2009; Ferrari et al. 2010). The essential features and assumptions of the improved affine approach used here can be summarized as follows:

- the equilibrium structure of the NS is determined by TOV equations, while its dynamical behaviour is governed by Newtonian hydrodynamics improved by the use of an effective relativistic scalar potential (Kampp & Janka 2002);
- the NS centre of mass moves in the tidal field of a Kerr BH along a simple inspiralling equatorial orbit (cf., eq. (21)) and each point of the orbit is associated with a BH timelike circular geodesic having the same radius;
- throughout the inspiral the NS remains a Riemann S-type ellipsoid, i.e., its spin and vorticity are parallel and their ratio is constant (see Chandrasekhar 1969);
- tidal effects on the orbital motion and the perturbation that the star induces on the BH are neglected.

For completeness, we next review the mathematical formulation of the affine model used here by writing the equations governing the NS deformations in the principal frame, i.e., the frame associated with the principal axes of the stellar ellipsoid. In this frame, the fluid variables of the affine model are five: the three principal axes of the stellar ellipsoid $a_1$, $a_2$ and $a_3$, the angular frequency of the internal fluid motion $\Lambda$ and the star’s spin $\Omega$ measured in the parallel-transported frame associated with the centre of mass of the star (Marck 1983).

The axis $a_3$ is perpendicular to the orbital plane, while $a_1$ and $a_2$ are perpendicular to $a_3$ (see Fig. 1). In the Newtonian limit ($M_{\text{BH}} \ll r$, where $M_{\text{BH}}$ is the BH mass and $r$ is the Boyer-Lindquist radial coordinate), $a_1$ and $a_2$ belong to the orbital plane. The dynamics of four of the five fluid variables is then governed by the following set of equations:

$$\ddot{a}_1 = a_1(\Lambda^2 + \Omega^2) - 2a_2\Lambda\Omega + \frac{1}{2} \frac{\dot{V}}{M} R_{NS}^3 a_1 \dot{A}_1 + \frac{R_{NS}^2}{M} \frac{\Pi}{a_1} c_{11} a_1 ,$$

$$\ddot{a}_2 = a_2(\Lambda^2 + \Omega^2) - 2a_1\Lambda\Omega + \frac{1}{2} \frac{\dot{V}}{M} R_{NS}^3 a_2 \dot{A}_2 + \frac{R_{NS}^2}{M} \frac{\Pi}{a_2} c_{22} a_2 ,$$

$$\ddot{a}_3 = \frac{1}{2} \frac{\dot{V}}{M} R_{NS}^3 a_3 \dot{A}_3 + \frac{R_{NS}^2}{M} \frac{\Pi}{a_3} - c_{33} a_3 ,$$

$$\dot{J}_z = \frac{\dot{M}}{R_{NS}^2} c_{12} (a_2^2 - a_1^2) ,$$

where the dots denote derivatives with respect to the proper time at the stellar centre $\tau$, the $c_{ij}$'s denote the components of the BH tidal tensor in the principal frame, $R_{NS}$ is the NS mass, $\dot{V}$ is the NS rate of mass decrease, and $\Pi$ is the NS rate of angular momentum decrease. The principal axes $a_1$, $a_2$ and $a_3$ are measured in the parallel-transported frame associated with the centre of mass of the star.
radius, and the index symbols $\tilde{A}_i$ are defined as
\[ \tilde{A}_i = \int_0^\infty \frac{d\sigma}{(a_1^2 + \sigma)(a_2^2 + \sigma)(a_3^2 + \sigma)} . \] (5)

The effective relativistic self-gravity potential for the isolated NS in spherical equilibrium $\tilde{V}$ and the scalar quadrupole moment for the isolated NS in spherical equilibrium $\tilde{\mathcal{M}}$ are given by
\[ \tilde{V} = -4\pi \int_0^{R_{\text{NS}}} \frac{[\dot{\varepsilon}(\tilde{r}) + \rho(\tilde{r})][m_{\text{TOV}}(\tilde{r}) + 4\pi\tilde{r}^3\dot{\rho}(\tilde{r})]}{\rho(\tilde{r})\tilde{r}^2 - 2m_{\text{TOV}}(\tilde{r})} \tilde{r}^3 \dot{\rho} d\tilde{r} , \] (6)
\[ \tilde{\mathcal{M}} = \frac{4\pi}{3} \int_0^{R_{\text{NS}}} \tilde{r}^4 \dot{\rho} d\tilde{r} , \] (7)
with $dm_{\text{TOV}}/d\tilde{r} = 4\pi\tilde{r}^2\dot{\epsilon}(\tilde{r})$. The pressure integral $\Pi$ is calculated as
\[ \Pi \equiv \int p(\rho) d\tilde{x} = 4\pi a_1 a_2 a_3 R_{\text{NS}}^3 \int_0^{R_{\text{NS}}} p \left( \frac{\dot{\rho}}{a_1 a_2 a_3} \right) \tilde{r}^2 d\tilde{r} , \] (8)
while
\[ J_s \equiv \frac{\tilde{\mathcal{M}}}{R_{\text{NS}}^3} [(a_1^2 + a_2^2)\Omega - 2a_1 a_2 + \Lambda] , \] (9)
is the spin angular momentum of the star. The fifth fluid variable can be expressed in terms of
\[ C \equiv \frac{\tilde{\mathcal{M}}}{R_{\text{NS}}^3} [(a_1^2 + a_2^2)\Lambda - 2a_1 a_2 + \Omega] , \] (10)
which is proportional to the circulation in the locally nonrotating inertial frame. We note that because we work in absence of viscosity, the circulation of the fluid is conserved, i.e., $\dot{C} = 0$. For simplicity, but also because this is the assumption made by all numerical-relativity simulations to date, we set $C = 0$ initially (the NS fluid is thus irrotational) so that (10) reduces to
\[ \Lambda = \frac{2a_1 a_2}{a_1^2 + a_2^2} \Omega . \] (11)

The components of the tidal tensor for a Kerr spacetime, expressed in the NS principal frame, are
\[ c_{11} = \frac{M_{\text{BH}}}{r^3} \left[ 1 - 3 \frac{r^2 + K}{r^2} \cos^2 (\Psi - \phi) \right] , \] (12)
\[ c_{22} = \frac{M_{\text{BH}}}{r^3} \left[ 1 - 3 \frac{r^2 + K}{r^2} \sin^2 (\Psi - \phi) \right] , \] (13)
\[ c_{12} = c_{21} = \frac{M_{\text{BH}}}{r^3} \left[ \frac{3}{2} \frac{r^2 + K}{r^2} \sin 2(\Psi - \phi) \right] , \] (14)
\[ c_{33} = \frac{M_{\text{BH}}}{r^3} \left( 1 + 3 \frac{K}{r^2} \right) , \] (15)
where the angle $\phi$ (which is related to $\Omega$ by $\dot{\phi} = \Omega$) is the angle that brings the parallel-transported frame into the principal frame by a rotation around the $a_3$ axis (Marck 1983). Similarly, $\Psi$ is an angle that governs the rotation of the parallel-transported tetrad frame in order to preserve the parallel transport of its basis vectors. Stated differently, the difference between $\Psi$ and $\phi$ represents the lag angle between the principal frame and the parallel transported one, i.e., $\phi_{\text{lag}} \equiv \Psi - \phi$, and thus measures how much the star is “lagging behind” in its orbit around the BH. If $\phi_{\text{lag}} = 0$ and thus $\Psi = \phi$, then the largest semi-major axis of the star is always pointing towards the BH. A schematic diagram of the BH-NS binary and of the relevant quantities discussed so far is shown in Fig. 1.

The constant $K$ appearing in the tidal-tensor components (12)–(15) is a linear combination of the energy $E$ and of the $z$-orbital angular momentum per unit mass of the star
\[ K \equiv (\dot{\alpha} E - L_z)^2 , \] (16)
where $\dot{\alpha} \equiv J/M$ is the spin of the BH and
\[ E \equiv \frac{r^2 - 2r M_{\text{BH}} + \dot{\alpha} \sqrt{r M_{\text{BH}}}}{r \sqrt{r^2 - 2r M_{\text{BH}} + \dot{\alpha} \sqrt{r M_{\text{BH}}}} , \] (17)
\[ L_z \equiv \frac{\sqrt{r M_{\text{BH}}(r^2 - 2\dot{\alpha} \sqrt{r M_{\text{BH}}}} + \dot{\alpha}^2)}{r \sqrt{r^2 - 2r M_{\text{BH}} + \dot{\alpha}^2}} . \] (18)

Note that because the tidal-tensor components $c_{11}$ and $c_{22}$ have a different sign, the forces acting on the corresponding semi-major axes $a_1$ and $a_2$ also have opposite signs and thus lead to a stretching of $a_1$ and a compression of $a_2$.

For simplicity, and to obtain a better agreement with the results of the numerical-relativity simulations, we will consider hereafter $\phi_{\text{lag}} = 0$ and thus $\phi = \Psi$. Furthermore, since we will consider a sequence of circular equatorial geodesics whose radius reduces due to the emission of gravitational radiation, the evolution of the angle $\Psi$ for each circular orbit is given by (Marck 1983)
\[ \dot{\Psi} = \sqrt{\frac{M_{\text{BH}}}{r^3}} , \] (19)
and thus also
\[ \dot{\phi} = \Omega = \sqrt{\frac{M_{\text{BH}}}{r^3}} . \] (20)
In order to evolve the equations of the affine model (1)-(5) we must select an equation of state (EOS) for the NS matter, specify the initial conditions and the evolution of the orbit. As far as the first is concerned, the model is sufficiently general that any EOS could be used and indeed several different ones were used in Ferrari et al. (2009). However, because here we want to compare with the results of numerical-relativity simulations and these have been performed mostly with a Γ law equation of state \( p = (\Gamma - 1) \rho \epsilon \) which for the adiabatic process considered in this paper is equivalent to a polytropic EOS \( p = K \rho^\Gamma \) with \( \Gamma = 2 \) or 2.75, we will here consider just polytropes with these polytropic exponents and present the result of more realistic EOSs in a subsequent work. As for the initial conditions, we consider an initial separation for the binary, \( r_0 \equiv r(t = 0) \) and set \( \phi_0 \equiv \phi(t = 0) = 0 \), where \( \Omega \) and \( \dot{\Omega} \) are automatically given by (20) and (11), respectively.

For the NS axes, instead, we set the time derivatives on the left hand sides of (1)–(3) to zero and solve the system for \( r, \theta, \phi \). For the time evolution of the orbital separation \( r \), we consider a very simple circular equatorial adiabatic inspiral (Misner et al. 1973), which accounts therefore for the radiative losses of two point masses at a 2.5 post-Newtonian (PN) approximation

\[
r(t) = r_0 \left(1 - \frac{t}{t_c}\right)^{1/4},
\]

where

\[
t_c = \left(\frac{5}{256}\right) \frac{r_0^4}{M_{NS} M_{BH} (M_{NS} + M_{BH})},
\]

is the inspiral time and \( M_{NS} \) is the gravitational mass of the NS. When generating the orbit, we make the approximation of setting

\[
dt = \frac{1}{dr}
\]

and therefore the orbit angle \( \theta \) evolves according to the simple equation

\[
\frac{d\theta}{dt} = \sqrt{\frac{M_{BH}}{r^3}}.
\]

It is important to remark that our goal is that of computing the mass of the torus produced by the tidal disruption and not an accurate description of the binary inspiral. In this sense, using a lower-order PN description of the orbit is very reasonable as the dynamics we are most interested in take place when the presently available PN models are no longer accurate.

Once the orbit is determined, we can integrate the affine-model equations determining the evolution when the ratio of the semi-major axes reaches a critical value \( (a_2/a_1)_{\text{crit}} \). This quantity cannot be determined a priori and is effectively a free parameter in our toy model. However, it may be tuned by comparing the results of the toy model with those of the numerical simulations and the way we do this will be discussed in the subsection. We thus define the tidal disruption radius \( r_{\text{tide}} \) as the orbital separation at which \( (a_2/a_1) = (a_2/a_1)_{\text{crit}} \).

A final quantity which is relevant to introduce and that may be useful to interpret the results of the toy model is the ISCO, which, for a generic Kerr BH is given by (Bardeen et al. 1972)

\[
r_{\text{ISCO}} = M_{BH} \left\{ 3 + Z_2 \mp [(3 - Z_2)(3 + Z_1 + 2Z_2)]^{1/2} \right\},
\]

where

\[
Z_1 = 1 + (1 - \tilde{a}^2/M_{BH}^2)^{1/3},
\]

\[
\times [(1 + \tilde{a}/M_{BH})^{1/3} + (1 - \tilde{a}/M_{BH})^{1/3}],
\]

\[
Z_2 = (3\tilde{a}^2/M_{BH}^2 + Z_1^2)^{1/2},
\]

(25)

where the upper/lower sign holds for co-rotating/counter-rotating orbits. In general, the ISCO is inside the tidal radius, i.e., \( r_{\text{ISCO}} < r_{\text{tide}} \), but there are situations in which the opposite is true and this is the case, for instance, when considering binary systems with very small mass ratios or stars with very large compactness. Also in these cases we follow the evolution of the axis ratio and “disrupt” the NS inside the ISCO as soon as the critical value is reached.

2.2 Neutron star disruption

As mentioned above, when the affine-model evolution of the mixed binary leads to the tidal disruption of the NS, we fragment the NS into fiducial fluid elements that would be representative of the motion of the NS matter. The first step in our strategy consists therefore in switching from the five fluid variables of the affine-model formulation to a description of the (disrupted) NS fluid as a set of test particles, each one of which possesses a mass, and a 4-velocity. In practice, at disruption we build a fine grid adapted to the ellipsoidal shape of the star and divide the star into a collection of fluid elements. In the principal frame, the centre of each fluid element is identified by a 3-vector \( \vec{x} \) and we calculate the mass of the corresponding fluid cell by multiplying the mass density at its centre by the volume of the fluid element. Moreover, we may associate to the centre of mass of each cell a 3-velocity, which, in the principal-axes frame, is given by (Chandrasekhar 1969)

\[
\vec{u} = \vec{u}_s + \vec{u}_c,
\]

(26)

where

\[
\vec{u}_s \equiv \frac{a_1}{a_2} \dot{\lambda}_x \vec{e}_1 - \frac{a_2}{a_1} \dot{\lambda}_x \vec{e}_2,
\]

(27)

is the spin velocity (i.e., the speed of the fluid due to its rotation), and

\[
\vec{u}_c \equiv \frac{\dot{\alpha}_1}{\alpha_1} \vec{e}_1 \times \vec{e}_1 + \frac{\dot{\alpha}_2}{\alpha_2} \vec{e}_2 \times \vec{e}_2 + \frac{\dot{\alpha}_3}{\alpha_3} \vec{e}_3 \times \vec{e}_3,
\]

(28)

is the ellipsoidal expansion/contraction velocity, \( \vec{e}_i \) being the unit vectors along the ellipsoid principal axis \( a_i \). The coordinate \( x_i \) along the \( i \)-th axis runs from \( -a_i \) to \( a_i \). With a rotation of an angle \( \phi \) around \( a_3 \), we switch from position 3-vectors in the principal frame to position 3-vectors in the parallel-transported tetrad associated with the NS centre of mass, where the 3-velocity \( \vec{u} \) becomes \( \vec{u} + \Omega \times \vec{x} \). In this parallel-transported tetrad, we determine the time component of each 4-velocity vector by exploiting the normalization condition \( u^{(a)} u_{(a)} = -1 \), and by recalling that the time component of the position vectors is simply \( x^{(0)} = 0 \). Finally, we express all the 4-position and the 4-velocity vectors in Boyer-Lindquist coordinates by applying the transformation laws derived in (Marcq 1983) and summarised in Appendix A.
The procedure described above provides a complete description, in Boyer-Lindquist coordinates, of the kinematical properties of fluid parcels as point particles freely-falling in a Kerr spacetime; this is what is needed to then estimate the torus mass.

2.3. Torus mass estimation

With the NS tidally disrupted and split into fiducial fluid elements of which we know the mass and the 4-velocity, we next make the assumption that the pressure gradients across neighbouring elements and the self gravity of the system play little role at the time of disruption and, subsequently, that the fluid elements effectively behave as independent collisionless fluid particles. As such, after disruption the NS is approximated as an ensemble of fluid particles which have a complex distribution of energy and angular momenta but are in free-fall towards the BH. When looking carefully at the dynamics of the NS in numerical-relativity simulations, in fact, it is quite striking how much the different parts of the disrupted star seem to behave like independent freely falling particles: the gravity of the black hole alone does seem to represent the tidal gravity of the black hole alone does seem to represent the dominant force at this stage of the evolution.

Using the 4-velocity of each particle we compute the corresponding conserved quantities by inverting the relations

\[
\frac{dt}{d\tau} = -\tilde{a}(\tilde{a} e \sin^2 \theta - \tilde{\ell}_z) + (\tilde{r}^2 + a^2)P/\Delta, \quad (29)
\]

\[
\left(\frac{dr}{d\tau}\right)^2 = P^2 - \Delta \left[ r^2 + (\tilde{\ell}_z - \tilde{a} e)^2 + Q \right], \quad (30)
\]

\[
\left(\frac{d\theta}{d\tau}\right)^2 = Q - \cos^2 \theta \left[ \tilde{a}^2(1 - e^2) + \tilde{\ell}_z^2 \sin^2 \theta \right], \quad (31)
\]

\[
\frac{d\phi}{d\tau} = -\tilde{a}(\tilde{a} e \sin^2 \theta - \tilde{\ell}_z \sin \theta) + \tilde{a} P/\Delta, \quad (32)
\]

where

\[P \equiv e(\tilde{r}^2 + \tilde{a}^2) - \tilde{\ell}_z \tilde{a}, \quad (33)\]

\[\Delta \equiv \tilde{r}^2 - 2\tilde{r} M_{BH} + \tilde{a}^2, \quad (34)\]

and \(e, \tilde{\ell}_z, \) and \(Q\) represent the energy, angular momentum and Carter’s constant of motion, respectively, all normalized to the mass of the particle. Note that it is necessary to use these general equations instead of equations (17) and (18) as the majority of the particles no longer follows circular equatorial geodesics.

As mentioned previously, we identify the mass of the remnant torus with the sum of the masses of the bound particles. In order to determine whether a given particle is bound or not we make use of (30) and note that a turning point occurs when \((dr/d\tau)^2\) passes through zero. Since the only influence of \(\theta\) is to decrease the overall magnitude of \((dr/d\tau)^2\) and to never change its sign, we only consider, without loss of generality, the case \(\theta = \pi/2\). We then use root-finding techniques for each particle and consider bound those particles for which \((dr/d\tau)^2 < 0\) at a radial position \(r_{TP}\) outside the event horizon \(r_{EH}\), such that \(r_{EH} < r_{TP} < r_{rad}\) [note that \((dr/d\tau)^2\) is always greater than 0 at \(r = r_{rad}\)] and simultaneously satisfy \(e < 1\). This final condition merely states that the gravitational binding energy has compensated the kinetic energy such that the total energy of the particle is less than the rest mass of the particle at infinity. When the mass accreted onto the BH has been computed, the mass of the BH is increased by this amount and the process is repeated. Once the relative difference in the mass of the torus is less than one part in one million, the process is terminated.

3. TUNING AND VALIDATION OF THE MODEL

In the affine-model approach based on a quasi-equilibrium approximation and discussed in Ferrari et al. (2009), the disruption radius is identified by the condition \(\left[\partial (a_2/a_1) / \partial r\right]^{-1} = 0\), i.e., as the radial separation at which the axis ratio diverges. Although this singular limit is clearly a shortcoming of the assumption of quasi-equilibrium, it is not obvious how to specify the tidal radius in a way which is not arbitrary to some extent. To remove at least in part this degree of arbitrariness we have decided to tune the tidal radius by carefully analyzing the results of recent numerical-relativity simulations and in particular those carried out at the AEI in Potsdam (Tonita et al. 2010), for which we have more direct control over the errors. When doing so we have realized that the axis ratio \(a_2/a_1\) is a robust measure across our simulations, but also when comparing with the simulations published in the literature. Hence, we have decided to monitor the axis ratio as the free parameter of our toy model and to identify the critical value which best represents the numerical data available.

As a result of this procedure we obtain \((a_2/a_1)_{\text{crit}} = 0.44\) and thus define the tidal radius as the orbital separation at which \((a_2/a_1)\) attains the critical value. It is reasonable to expect that \((a_2/a_1)_{\text{crit}}\) will depend on the BH spin and on the mass ratio. Here, however, we assume that such dependence is weak and thus set it to be constant. As we discuss below, even with this crude approximation we can reproduce most of the numerical results with an error which is below \(\sim 15\%\).

As an addition note, we stress that although robust (i.e., a single choice fits well all of the available data), the masses of the tori are rather sensitive to the choice for the critical axis ratio. In particular, for the same binary, a change of \(\sim 2\%\) in \((a_2/a_1)_{\text{crit}}\) (i.e., a change in the last significant figure) may lead to a change in the last significant figure of the estimated torus mass, and thus up to a \(\sim 50\%\) change for cases with a very small remnant mass. This effect disappears if one tunes \((a_2/a_1)_{\text{crit}}\) with an extra significant digit.

Before going to the details of the comparison with the numerical simulations it is worth making two remarks. The first one is that after having identified in the axis ratio a consistent parameter which we constrain to the second significant figure, we also expect that it will be further refined as new and more accurate results from numerical simulations become available. The second one has already been made in the introduction and stresses the fact that the numerical data itself does not show a great degree of consistency. While there are two cases which have been considered by more than one group, most of the data available refers to configurations which are slightly different and hence difficult to compare. Nevertheless, it is remarkable that even for the same configurations (cf., the eighth and the twelfth rows in Table 2.3), or some which are not very different (cf., the fifth and ninth rows in Table 2.3), the numerical results yield tori whose masses differ considerably. Interestingly, the predictions of the toy model are equally distant from the numerical results reported in the eighth and the twelfth rows, thus suggesting that both simulations may be equally imprecise.

Being a toy model, its validity is constrained to within specific ranges of the space of parameters, which we discuss below and which allow us nevertheless to cover essentially all
of the complete space of parameters. The first constraint on the range of validity comes from the mass ratio, which cannot be too large since the affine model assumes that the NS spirals as a test fluid and is therefore increasingly more accurate the smaller the mass ratio. As a result, we will consider only binaries with mass ratios

$$0.10 \leq q \leq 0.33.$$  

While this condition removes several of the values reported in Shibata et al. (2009), it is not at all unrealistic. We recall, in fact, that the most recent estimates for the mass accreted onto the primary compact object during the common-envelope phase are rather low and thus the BH masses in close BH-NS binaries are likely to fall primarily in values near $M_{\text{BH}} \approx 10 M_\odot$ (Belczynski et al. 2007). Considering a canonical 1.4 $M_\odot$ NS, BH-NS systems are therefore most likely to come in a mass ratio that is $q \approx 0.14$.

The second constraint comes from the stellar compactness, which cannot be too small for a relativistic compact star nor too large given the test-fluid hypothesis of the affine model. As a result, we will consider only binaries where the NS has

$$0.1 \leq C \leq 0.16.$$  

This range covers well the one considered so far in numerical simulations (cf. Table 2.3), but it is worth remarking that the recent arguments made in Ozel et al. (2010) suggest a rather high and generic compactness, $C \sim 0.16$, which is at the edge of the range considered here, and that a standard cold EOS, such as the APR (Akmal et al. 1998) EOS, leads on average to compactnesses $C \sim 0.18$, thus outside of the range considered here. Future simulations in which this EOS is employed will help extend the range of validity in compactness of the toy model.

The third constraint comes from the BH spin, which we cannot take as too large given we that treat the motion of the disrupted NS with geodesics and these would lead to incorrect results if the dimensionless spin parameter $a \equiv J/M_{\text{BH}}^2$ is too high (e.g., the ratio $M_{b,\text{tor}}/M_{b,\text{NS}} \to 1$ for $a \to 1$). As a result, we will consider only binaries where the BH has

$$0.0 \leq a \leq 0.85.$$  

The fourth and final constraint comes from the mass of the torus, for which we need a lower limit. This is even true for numerical simulations, whose precision is not infinite. As a result, we consider the tori to have a zero baryonic mass if

$$M_{b,\text{tor}} \leq 0.01 M_{b,\text{NS}} \simeq 0.014 M_\odot.$$  

The results of the comparison are summarized in Table 2.4, where, in addition to our numerical simulations (Tonita et al. 2010), we have considered also the data reported in Duez et al. (2010), Etienne et al. (2009), and Shibata et al. (2009). The parameters of each BH-NS binary are reported in the first four columns of the table: these are the adiabatic index $\Gamma$ of the NS EOS, the NS compactness $C$, the binary mass ratio $q$, and the initial BH spin $a$, which does not change from its initial value in our toy model. The last three columns provide instead the baryonic torus masses $M_{b,\text{tor}}$ obtained from the toy model or by the fully general-relativistic calculations (both in units of the NS baryonic mass $M_{b,\text{NS}}$), and the relative percentage error.

A rapid inspection of the Table and in particular of its last column clearly shows that there are four out of sixteen numerical relativity results that have rather large errors, i.e., between 50 and 100%. Not having a clear measure of the error associated with those simulations, it is hard to judge whether this is a limit of the toy model or whether this is a limit of the numerical simulations. It should be remarked, however, that these simulations are those which report tori masses that are close to the limit we consider reasonable (i.e., $M_{b,\text{tor}}/M_{b,\text{NS}} \simeq 0.01$) and clearly new simulations of those binaries are necessary to settle these differences. However, with the exception of those cases, the Table also reveals that the toy model can

</table>
reproduce the remaining cases (which represent three quarters of the data available) with an error which is at most 18% and is virtually 0 for most of the cases. Considering that the numerical-relativity simulations in Table 2.3 were performed with different codes, different initial separations and amounts of eccentricity\(^5\), we believe that the tuning made for the toy model is both reasonably robust and accurate.

Before concluding this Section on the tuning of our toy model, it is important to note that the choice of a critical value for the axis ratio \((a_2/a_1)_{\text{crit}}\) also allows us to determine the ratio between the NS self-gravity and the tidal forces. Using a well-known Newtonian argument, the ratio between the gravitational and tidal force for a fluid element on the stellar surface when the binary is at the separation \(r_{\text{tide}}\) is

\[
\left(\frac{M_{\text{NS}}}{M_{\text{BH}}}\right) \left(\frac{r_{\text{tide}}}{a_1}\right)^3 = \mathcal{R},
\]

so that when \(\mathcal{R} = 1\) the tidal and gravitational forces are equal. Using the affine model and considering the tidal radius as the one at which \((a_2/a_1) = (a_2/a_1)_{\text{crit}} = 0.44\), we can compute the values of the two forces at tidal disruption. Doing so when considering the binaries evolved in Tonita et al. (2010) which yield a torus, we find \(\mathcal{R} \approx 2.2 - 2.9\). Stated differently, our tuning reveals that the tidal disruption begins much earlier than one would naively think and when the tidal force is only \(\sim 1/4\) the gravitational one.

4. RESULTS

Having tuned and validated the model, we will next consider its predictions for the baryon mass of the torus as a function of the mass ratio \(q\), the stellar compactness \(C\), and the BH spin \(a\). Because this space of parameters is three-dimensional, it is more convenient to consider constant-spin slices and hence we will first comment on a fiducial case of a spinning BH with \(a = 0.4\) and then discuss how these results change across the possible values of the spin.

Most of our results are summarized in Fig. 2 which shows the baryonic mass of the torus in units of the stellar mass, \(M_{\text{b,tor}}/M_{\text{b,NS}}\), as a function of the stellar compactness \(C\) and of the binary mass ratio \(q\). The data referring to a binary in which the BH has a dimensionless spin parameter \(a = 0.4\). Quite clearly, the final mass in the torus varies considerably across the possible values of parameters and is systematically larger the smaller \(C\). This is rather obvious: the smaller the compactness, the more “Newtonian” the star will be and thus with a smaller effective gravity at the surface. In turn, this means that, all else equal, it will be easier to disrupt it even at large distances from the BH (i.e., \(r_{\text{tide}}\) is comparatively large) and hence produce a larger torus.

At the same time, Fig. 2 shows that the mass in the torus will be larger when the BH and the NS have comparable masses. Also this result is quite obvious: the smaller the mass ratio, the more unlikely it will be for the star to be tidally disrupted and to be accreted “whole” by the BH. Putting things together, a BH-NS system with large mass ratio and small compactness maximizes the yields in terms of torus mass. For the same reasons, a binary with small mass ratio and large compactness will yield the smallest tori. To fix the ideas: for a BH-NS system with \(a = 0.4\), the toy model predicts that

\[M_{\text{b,tor}}/M_{\text{b,NS}} \sim 0.5\] when \(C = 0.10\) and \(q = 0.33\), while essentially no tori are produced for \(q \lesssim 0.14\) and \(C \gtrsim 0.14\) (cf., third panel of Fig. 2 where this data is also shown with contour plots). Overall, our toy model suggests that at least statistically a BH with spin larger than \(\sim 0.4\) is necessary to produce any astrophysically relevant torus.

The generic predictions of the toy model for \(a = 0.4\) remain unchanged when considering also other BH spins, extending smoothly from smaller to larger spins. This is summarized in Fig. 3 where different panels from top to bottom refer to \(a = 0.0, 0.2, 0.4, 0.6, 0.8, 0.85\), respectively. The baryonic mass of the torus is still in units of the NS mass and is reported as a function of the compactness and of the mass ratio, but it is shown through contour plots to better quantify the results. The numerical values of some representative contour lines are shown and allow for a direct measurement (the contours are equally spaced in a linear scale), while the thick and black solid line shows the area below which no torus is created (i.e., the “no-torus” area with \(M_{\text{b,tor}}/M_{\text{b,NS}} < 0.01\)). Finally, shown with a horizontal dot-dashed line is the most likely mass ratio for a canonical 1.4 \(M_\odot\) NS.

Moving from the top to the bottom of Fig. 3 it is easy to recognize that the maximum mass attained at the smallest compactness increases significantly with the BH spin, ranging from \(M_{\text{b,tor}} \approx 0.18M_{\text{b,NS}} \approx 0.25M_\odot\) for \(a = 0.0\), to \(M_{\text{b,tor}} \gtrsim 0.95M_{\text{b,NS}} \gtrsim 1.33M_\odot\) for \(a = 0.85\). At the same time, the “no-torus” area decreases and virtually disappear for \(a \gtrsim 0.6\). Stated differently, for sufficiently large BH spins a torus is always produced and with non-negligible mass. As an example, taking as fiducial compactness the canonical value of \(C \approx 0.145\), the torus mass at the fiducial mass ratio goes from \(M_{\text{b,tor}} \approx 0.06M_{\text{b,NS}} \approx 0.08M_\odot\) for \(a = 0.4\), to \(M_{\text{b,tor}} \approx 0.24M_{\text{b,NS}} \approx 0.34M_\odot\) for \(a = 0.85\).

A complementary view, because it refers to a different slicing of the space of parameters, is illustrated in Fig. 4 which is the same as in Fig. 3 but it shows the baryonic torus mass as a function of the BH spin and of the mass ratio for a fixed compactness \(C = 0.145\) (left panel), or as a function of the BH spin and of the compactness for a fixed mass ratio \(q = 0.14\) (right panel). Both panels of the figure are
Fig. 3.— Baryonic torus mass in units of the stellar mass $M_{b,\text{tor}}/M_{b,\text{NS}}$ shown as a function of the compactness $C$ and of the mass ratio $q$. From top to bottom the different panels refer to different values of the BH spin ($a = 0.0, 0.2, 0.4, 0.6, 0.8, 0.85$) and the numbers on the iso-mass contours indicate the constant spacing. Shown with a thick and black solid line is the area below which no torus is created (i.e., the “no-torus” region with $M_{b,\text{tor}}/M_{b,\text{NS}} < 0.01$), while shown with a horizontal dot-dashed line is the most-likely mass ratio for a canonical $1.4 \, M_\odot$ NS.
rather self-explanatory and underline what has already been discussed above: large tori masses are possible for BHs which are spinning sufficiently rapidly or for neutron stars which are not very compact (favoring stiff equations of state).

In summary: considering an astrophysically realistic mass ratio $q \simeq 0.14$ and a conservative value of the stellar compactness $C \simeq 0.145$ (we recall that even larger values were recently suggested in [Ozel et al. (2010)], the predictions of the toy model are that the torus mass should be

$$M_{b,\text{tor}} \lesssim 0.24 M_{b,\text{NS}} \simeq 0.34 M_\odot,$$

for BH spins $0 \leq a \leq 0.85$. Such masses are comparable but also smaller than the ones predicted by the analysis of unequal-mass NS-NS mergers carried out by [Rezzolla et al. (2010)].

5. AN INTUITIVE INTERPRETATION

In the previous Section we have shown that the complex dynamics of the tidal disruption and subsequent accretion onto the BH is well-captured by the simple assumptions needed to build our toy model. In what follows we will show that an even simpler framework can be built to explain at least qualitatively the results of the toy model.

We have already noted that binaries with less compact NSs produce bigger tori as these are more “Newtonian” and hence can sustain smaller tidal forces before being disrupted. Stated differently, less compact stars have larger tidal radii $r_{\text{tide}}$. In the usual arguments this quantity is generally compared to the ISCO, and the standard line of arguments says that a BH-NS binary will produce a torus if $r_{\text{tide}} \gtrsim r_{\text{ISCO}}$. This reasoning, however, is inadequate for systems which yield low mass tori. An obvious failure of the argument is offered by a NS that is disrupted by its BH companion exactly at $r_{\text{tide}} = r_{\text{ISCO}}$. In this case half of the star would still be outside the ISCO and thus potentially capable of producing a torus.

The necessary, but not sufficient, condition for a BH-NS binary to yield a torus is thus better expressed as

$$\frac{r_{\text{tide}} + a_1(r_{\text{tide}} - r_{\text{ISCO}})}{2R_{\text{NS}}} \simeq 1 + \frac{r_{\text{tide}} - r_{\text{ISCO}}}{2R_{\text{NS}}} > 0,$$

where the second expression is obtained after recognizing that at tidal disruption $a_1(r_{\text{tide}}) \simeq 2R_{\text{NS}}$. Expression (37) has three important properties: it is dimensionless, it combines the three fundamental lengthscales of our system, and it essentially measures how many NS diameters fit between $r_{\text{tide}} + a_1(r_{\text{tide}})$ and $r_{\text{ISCO}}$ (cf., Fig. 1). In other words, (37) quantifies how much useful space there is for the NS to form a torus after it is tidally disrupted.

At this point it is natural to associate this quantity directly to the mass of the torus as expressed in units of the NS mass

$$\frac{M_{b,\text{tor}}}{M_{b,\text{NS}}} \simeq k \left[ 1 + \frac{r_{\text{tide}} - r_{\text{ISCO}}}{2R_{\text{NS}}} \right],$$

where $k$ is in principle a function of $q$ and $C$, but can be in practice be taken to be simply a constant. Not surprisingly, (38) reproduces, at least qualitatively, all of the phenomenology discussed before and predicted by our toy model. As an example, for a fixed BH spin, and hence fixed $r_{\text{ISCO}}$, the torus mass will increase for less compact NSs since for these $r_{\text{tide}}$ will grow and more rapidly than $R_{\text{NS}}$. Similarly, for a fixed compactness, and hence for a fixed $R_{\text{NS}}$, the torus mass will grow with the BH spin as does the difference $r_{\text{tide}} - r_{\text{ISCO}}$, $r_{\text{ISCO}}$ decreases more rapidly than $r_{\text{tide}}$.

6. CONCLUDING REMARKS

The production of a massive torus orbiting stably around a rotating BH is a necessary ingredient in all of those models that explain SGRBs in terms of the coalescence of binary systems composed of a BH and a NS or of two NSs. The accurate calculation of this mass inevitably requires the use of numerical-relativity simulations, which however are still very expensive and have so far been applied only to a tiny patch of the possible space of parameters. In the case of BH-NS binaries especially, the space of parameters is particularly extended as it involves the mass ratio of the binary $q$, the stellar compactness $C$, and the BH spin $a$. As a result, we presently have only a very limited idea of what are the likely torus masses that this process will yield and hence have a rather limited ability to assess whether or not the merger of a BH-NS system under astrophysically realistic conditions will serve as
a robust scenario for the powering of SGRBs.

To compensate for this lack of knowledge, we have developed a toy model that allows for the computation of the mass of the torus without having to perform a numerical relativity simulation. In essence, we model the NS in the binary as a tri-axial ellipsoid which is tidally distorted as it orbits in the tidal field of a rotating BH and as described by the relativistic affine model. When the star is disrupted, we decompose it into a system of non-interacting “fluid particles” which move on the corresponding geodesics. We therefore compute the ratio of the semi-major axes on the equatorial plane and with the aid of numerical-relativity simulations. The tuning requires care, but allows us to reproduce with precision the predictions that our toy model can make quantitatively.

Toy models are by construction approximate representations of much more complex phenomena and their predictions are therefore intrinsically accompanied by errors. Bearing this in mind, the toy model presented here can be further improved as new and more accurate numerical-relativity simulations are performed and as their level of realism increases with the inclusion of microphysical EOSs, magnetic fields and radiative transfer. This will represent the focus of our future work.

It is a pleasure to thank Bruno Giacomazzo and Jocelyn Read for useful discussions. APPENDIX

THE PARALLEL PROPAGATED TETRAD

In this Appendix we gather together the equations derived by Marck (1983) to define a tetrad which is parallel-transported as it moves along a timelike geodesic of a Ker BH spacetime in Boyer-Lindquist coordinates

$$ds^2 = -\left(1 - \frac{2M_{BH}}{\Sigma}\right)dt^2 - \frac{4M_{BH}}{\Sigma} \bar{a} \sin^2 \theta dtd\phi + \frac{\Sigma}{\Delta} dr^2 + \Sigma d\theta^2 + \frac{A}{\Sigma} \sin^2 \theta d\phi^2,$$  \hspace{1cm} (A1)

where

$$\Sigma \equiv r^2 + \bar{a}^2 \cos^2 \theta,$$  \hspace{1cm} (A2)

$$\Delta \equiv r^2 + \bar{a}^2 - 2M_{BH}r,$$  \hspace{1cm} (A3)

$$A \equiv (r^2 + \bar{a}^2) - \Delta \bar{a}^2 \sin^2 \theta.$$  \hspace{1cm} (A4)

In our model, the test particle is identified with the centre of mass of a NS orbiting its rotating BH companion. Marck expresses his results in the canonical symmetric orthonormal tetrad introduced by Carter (1968)

$$\omega^{(0)} = \sqrt{\frac{\Delta}{\Sigma}} (dt - \bar{a} \sin^2 \theta d\phi),$$  \hspace{1cm} (A5)

$$\omega^{(1)} = \sqrt{\frac{\Delta}{\Sigma}} dr,$$  \hspace{1cm} (A6)

$$\omega^{(2)} = \sqrt{\Sigma} d\theta,$$  \hspace{1cm} (A7)

$$\omega^{(3)} = \frac{\sin \theta}{\sqrt{\Sigma}} [\bar{a} dt - (r^2 + \bar{a}^2)d\phi],$$  \hspace{1cm} (A8)

which has the convenience of casting the Kerr metric in the form

$$ds^2 = \eta_{(\mu)(\nu)} \omega^{(\mu)} \omega^{(\nu)},$$  \hspace{1cm} (A9)
where $\eta_{\mu\nu} = \text{diag}(-1, 1, 1, 1)$ is the metric tensor of Minkowski spacetime. Before expressing the components of the basis vectors of the tetrad found in Marck (1983), we define the quantities $\alpha$ and $\beta$

$$\alpha \equiv \sqrt{\frac{K - \tilde{a}^2 \cos^2 \theta}{r^2 + K}}, \quad (A10)$$

$$\beta \equiv \sqrt{\frac{r^2 + K}{K - \tilde{a}^2 \cos^2 \theta}}, \quad (A11)$$

where $K$ is Carter’s constant, and the two vectors

$$\tilde{e}_1^{(0)} = \alpha \sqrt{\frac{\Sigma}{K \Delta}} \dot{r}, \quad (A12)$$

$$\tilde{e}_1^{(1)} = \frac{\alpha r [E (r^2 + \tilde{a}^2) - \tilde{a} L_z]}{\sqrt{K \Sigma \Delta}}, \quad (A13)$$

$$\tilde{e}_1^{(2)} = \frac{\beta \tilde{a} \cos \theta (\dot{a} E \sin \theta - L_z \sin^{-1} \theta)}{\sqrt{K \Sigma}}, \quad (A14)$$

$$\tilde{e}_1^{(3)} = \beta \sqrt{\frac{\Sigma}{K}} \tilde{a} \cos \theta \dot{\theta}, \quad (A15)$$

and

$$\tilde{e}_2^{(0)} = \frac{\alpha r [E (r^2 + \tilde{a}^2) - \tilde{a} L_z]}{\sqrt{\Sigma \Delta}}, \quad (A16)$$

$$\tilde{e}_2^{(1)} = \alpha \sqrt{\frac{\Sigma}{\Delta}} \dot{r}, \quad (A17)$$

$$\tilde{e}_2^{(2)} = \beta \sqrt{\Sigma} \dot{\theta}, \quad (A18)$$

$$\tilde{e}_2^{(3)} = \beta \tilde{a} E \sin \theta - L_z \sin^{-1} \theta \sqrt{\Sigma}, \quad (A19)$$

where the dots indicate derivatives with respect to the proper time $\tau$, and where $E$ and $L_z$ are, respectively, the energy and the angular momentum about the axis of symmetry of the BH per unit mass of the star. We are now ready to express – in Carter’s symmetric tetrad – the components of the vectors forming an orthonormal tetrad parallel-transported along an arbitrary timelike geodesic in a Kerr spacetime. These are

$$e_0^{(0)} = \frac{E (r^2 + \tilde{a}^2) - \tilde{a} L_z}{\Delta \sqrt{\Sigma}}, \quad (A20)$$

$$e_0^{(1)} = \sqrt{\frac{\Sigma}{\Delta}} \dot{r}, \quad (A21)$$

$$e_0^{(2)} = \sqrt{\Sigma} \dot{\theta}, \quad (A22)$$

$$e_0^{(3)} = \frac{\tilde{a} E \sin \theta - L_z \sin^{-1} \theta}{\sqrt{\Sigma}}, \quad (A23)$$

$$e_1 = \cos \Psi \tilde{e}_1 - \sin \Psi \tilde{e}_2, \quad (A24)$$

$$e_2 = \sin \Psi \tilde{e}_1 + \sin \Psi \tilde{e}_2, \quad (A25)$$

and

$$e_3^{(0)} = \sqrt{\frac{\Sigma}{K \Delta}} \tilde{a} \cos \theta \dot{r}, \quad (A26)$$

$$e_3^{(1)} = \frac{\tilde{a} \cos \theta [E (r^2 + \tilde{a}^2) - \tilde{a} L_z]}{\sqrt{K \Sigma \Delta}}, \quad (A27)$$

$$e_3^{(2)} = -\frac{r (\dot{a} E \sin \theta - L_z \sin^{-1} \theta)}{\sqrt{K \Sigma}}, \quad (A28)$$

$$e_3^{(3)} = \sqrt{\frac{\Sigma}{K}} r \dot{\theta}. \quad (A29)$$

The rotation by an angle $\Psi$ in (A24) and (A25) ensures that $e_1^{(1)}$ and $e_2^{(2)}$ are indeed parallel-transported along any Kerr timelike geodesic. Finally, the evolution of the angle $\Psi$ is governed by (19) for circular equatorial orbits.
