Abstract

A zirconium oxynitride catalyst was used for the decomposition of ammonia to hydrogen and nitrogen. The onset of catalytic activity at \( \sim 550 \) °C coincided with the onset of nitrogen ion mobility in the material and a phase change from the initial \( \beta' \) phase (\( \sim Zr_7O_{11}N_2 \)) to the nitrogen-rich \( \beta'' \) ZrON phase (\( \sim Zr_7O_{9.5}N_3 \)). No hydrazine formation during an extended time on stream was detectable. Moreover, the onset of activity was also correlated to a rapid change in the electronic structure of the surface accompanying formation of the more active \( \beta'' \) ZrON phase. The results presented here show for the first time a direct correlation among the onset of ion conductivity as a bulk property, a modified electronic structure of the surface, and the catalytic performance of a heterogeneous catalyst.
